A CASE OF HIGHLY ABNORMAL BLOOD GROUP ASSOCIATED WITH AUTO-AGGLUTINATION IN THE COLD.

By R. B. LLOYD, M.A., M.B., B.chir. (Cantab.),

LIEUTENANT-COLONEL, I.M.S.,

Imperial Serologist,

and

S. N. CHANDRA, M.B.,

Officiating Assistant Serologist.

(Results expressed in the international nomenclature.)

S. B., a Muhammadan female aged 26, was admitted to the Eye Infirmary of the Medical College Hospital, Calcutta, under the care of Mr. Ahmed, with the diagnosis of anæmia with cataract. The spleen was enlarged, the Wassermann reaction was negative, and there had been no previous blood transfusion. As it was desired to perform a blood transfusion, specimens of citrated cells and of whole blood were sent to us as usual for blood grouping tests and selection of a suitable blood donor.

Her washed cells tested for iso-agglutination against sera of known groups yielded the following reactions:—

With group O serum +.

With group A serum +.

With group B serum +.

Therefore as judged from her cells her blood group is AB. Her serum tested for iso-agglutination against cells of known groups yielded the following reactions:—

With group A cells +.

With group B cells +.

These serum reactions are highly abnormal in a blood whose cells are of group AB.

We accordingly drew a fresh blood sample from the patient and retested her washed cells and serum, respectively, with several different sets of grouping sera and cells of known group. The results were identical with those shown above. As it was evident we had to deal with a very extraordinary case, full investigation was carried out.

Routine blood examination showed the following:—

Hæmoglobin	..	40 per cent.
Red cell count	..	3,250,000* per c. mm.
White cell count	..	3,700 per c.mm.
Differential white cell count:—		
Polymorphonuclears	..	55 per cent.
Small mononuclears	..	34 "
Large mononuclears	..	6 "
Large hyalines	..	2 "
Eosinophiles	..	3 "

* This later fell to 2,000,000 per c.mm.

abnormal iso-agglutination reactions being discovered, the blood should be classified as to group according to the reactions of the cells (agglutinogens) and not according to the serum reactions (agglutinins). On this basis the group of the patient is AB (Moss group I). It follows that this blood does not fall into the category of the so-called "defect types." On the contrary, additional factors are present, as the serum agglutinated both group A cells and group B cells, which should not be the case.

We may now record and analyse the numerous experiments performed to elucidate the nature of the abnormality.

1. The cells of the patient were again tested against a known group O serum. The reactions of this particular group O serum were fully controlled against known cells of groups A and B and were completely normal. The agglutination was positive. The group of the patient being assumed to be AB, this experiment with group O serum must yield a positive agglutination.

2. The cells of the patient were also tested against four different fully controlled sera of group A, with positive agglutination in each case. With cells assumed to be of group AB, these reactions must necessarily be positive.

3. Similarly, the cells of the patient were tested against four different fully controlled sera of group B, again with positive agglutination in each instance. With cells believed to be of group AB, all these reactions must necessarily be positive.

4. The patient's serum was now tested against the cells of a normal case of group AB. The agglutination was positive. Herein lies the abnormality. A serum from a blood containing cells provisionally grouped AB here agglutinates the cells of a blood definitely known to be of group AB. We may now provisionally conclude that agglutinins are present in the patient's serum which are not in accordance with Landsteiner's rule.

5. The patient's serum was also tested against the cells of four persons of group A. The agglutination was positive in each case. With a normal serum of group AB these reactions should, of course, be negative; but this abnormal case of assumed group AB is here seen to contain an agglutinin for group A cells.

6. The patient's serum was similarly tested against the cells of five persons of group B. The agglutination was positive in each case, showing the presence also of an agglutinin for group B cells.

As agglutinins effective against both group A cells and group B cells are present, the reason for the positive agglutination of the normal group AB cells in experiment 4 will be evident.

7. The patient's serum was tested for agglutination against her own washed cells. The

was negative. There is thus at laboratory temperature no evidence of auto-agglutination.

8. The patient's serum was tested for agglutination against her own washed cells in the refrigerator. The result was positive. There is thus definite evidence of auto-agglutination in the cold. This will be referred to in greater detail below.

9. The patient's cells were incubated for two hours at 37°C. with a normal group O serum. After the incubation, the serum was separated and tested for agglutination against cells of group A and group B, yielding a completely negative reaction in each case. The patient's cells can thus absorb from group O serum both the anti-A and anti-B agglutinins, thereby showing the presence in the patient's cells of both A and B agglutinogens. This confirms the correctness of the assumption that the true group of the patient is AB.

10. The serum of the patient was now absorbed with cells of group A for two hours in the incubator at 37°C. After removal of the cells the serum was tested for agglutination against cells of groups AB, A and B with results as under:—

With cells AB +.
With cells A —.
With cells B +.

This experiment has removed the anti-A agglutinin from the patient's serum.

11. Similarly, the serum of the patient was absorbed with cells of group B under the same conditions. After removal of the cells the serum was tested against cells of groups AB, A and B with results as under:—

With cells AB +.
With cells A +.
With cells B —.

This experiment has removed the anti-B agglutinin.

12. Similarly, the patient's serum was absorbed with group AB cells under the same conditions, and after separation of the cells the absorbed serum was tested against cells AB, A and B with results as under:—

With cells AB —.
With cells A —.
With cells B —.

Clearly, both the agglutinins have now been removed.

The last three experiments show that the patient's serum contains both the anti-A and the anti-B agglutinins, and that they may be removed by absorption either separately or together. We therefore reach the extraordinary conclusion that both anti-A and anti-B agglutinins are present in this patient's blood along with the A and B agglutinogens, a condition which involves an infringement of Landsteiner's rule, and which one would suppose to be incompatible with life. Yet, as we have seen, the patient's serum does not agglutinate her own

cells at laboratory temperature (25°C.). The patient's serum agglutinates her own cells sharply at refrigerator temperature (approximately 8°C.).

We may now consider experiments which were carried out to ascertain if this auto-agglutination in the cold had any bearing on the anomalous grouping reactions described above.

13. The patient's serum was again tested for agglutination in the refrigerator against her own washed cells. The result was, as above noted, positive. The preparation was left in the refrigerator for two hours. It was then removed and divided into two parts:—

(i) *The smaller portion.*—This was placed in the incubator at 37°C. to see if the agglutination disappeared. The positive reaction completely disappeared, i.e., the reaction is reversible.

(ii) *The larger portion.*—This was centrifuged as rapidly as possible and after centrifugation the separated serum was tested for agglutination against cells of group A and group B. The results were positive in both cases.

It was naturally not possible to carry out centrifugation at refrigerator temperatures, but we think it probable that in this last experiment we have removed the auto-agglutinin from the patient's serum. After the absorption the abnormal agglutination of both group A cells and group B cells still persists.

We conclude accordingly that although this patient's serum exhibited a high degree of auto-agglutination in the cold, yet this is not the cause of the highly abnormal blood group. It would thus seem that in exceptional circumstances it is possible for a blood to contain both the A and B agglutinogens and both the anti-A and anti-B agglutinins, and yet in some unexplained way not to show auto-agglutination either *in vivo*—this presumably never occurs—or *in vitro* at laboratory temperatures (25°C.).

The surgeon in charge of this case was advised that blood transfusion might be followed by a grave accident, and that we were not prepared to pass any blood donor as safe for the purpose.

In view of the possibility that this abnormality might be familial, we attempted to obtain blood samples from the patient's near relations. Of these we were only able to examine one, a brother aged 45. On grouping he was found to be an entirely normal instance of group AB, i.e., the same group as the "fundamental" group of the patient. His serum also sharply agglutinated his own washed cells in the refrigerator. The test for reversibility was inconclusive.

The technical methods used by us for some years now for the determination of blood groups have been closely considered in their theoretical aspects and extensively tested in practice, and they have invariably yielded extremely satisfactory results.

We may conclude this article by a reference to certain forms of hæmaglobin.

which, though non-specific and independent of the four group scheme, may yet produce a result somewhat similar to that produced by the genuine iso-agglutination. These allied reactions have consequently an important bearing on the controls required in a technically correct blood grouping procedure.

This subject is a somewhat complicated one, and a brief precise statement which would cover all the recorded observations is not possible, the more so as the explanations offered by different workers are not in all cases in complete accord. It may be said, however, that there are two main types of "false reactions" which may be sharply distinguished both from genuine iso-agglutination and from one another. These two types are now termed "pseudo-agglutination" and "auto-agglutination."

Pseudo-agglutination.—It is well known that under certain conditions, especially in inflammatory diseases, the blood cells tend to settle unusually rapidly, leading to the formation of a buffy coat. This is a normal phenomenon in horse blood. The work of Shattock and of Lattes has shown that this phenomenon, termed pseudo-agglutination, is due to exaggeration of the normal power of the serum to aggregate the erythrocytes in the form of rouleaux. Shattock showed that this form of clumping disappears on slight dilution, 1:2, 1:3. The active principle by which this form of clumping is brought about is non-specific and non-absorbable by red cells. These two characteristics and the disappearance of the positive reaction on slight dilution serve to distinguish this phenomenon from the genuine iso-agglutination occurring in accordance with the four group scheme. As in iso-agglutination, temperature changes have little influence on pseudo-agglutination. The practical deduction in the development of an accurate blood grouping technique is that sufficient dilution of the reagents must be ensured.

The possibility of pseudo-agglutination must be borne in mind when applying blood grouping tests in the forensic examination of bloodstains, as under these conditions there is a tendency to employ the reagents in too great concentration.

Pseudo-agglutination may, according to Lattes, be avoided by receiving the erythrocytes into a specially prepared solution of lecithin.

Auto-agglutination.—Cells may be agglutinated by their own serum at refrigerator temperatures (5 to 10°C.). This phenomenon is apt to undergo considerable intensification in certain pathological conditions, of which anæmia and trypanosomiasis are prominent examples. The reaction occurs only in the cold, and is reversible. This is the "cold agglutination" of Amzel and Hirsfeld, or the "panagglutination" of Mino. If cells thus agglutinated in the refrigerator by their own serum are washed with ice cold saline, and the preparation warmed to room temperature, the cell clumps break up, and the previously absorbed auto-agglutinin is set free. If the preparation be now centrifuged, the supernatant saline, which

now contains the auto-agglutinin, will again agglutinate red cells at refrigerator temperatures. The auto-agglutinin, though non-specific, is thus absorbable, differing in the former respect, though similar in the latter, to the genuine iso-agglutinin. The outstanding distinction is of course the fact that auto-agglutination vanishes at 37°C., and is hardly at all in evidence at room temperatures, and certainly cannot in India be confused with iso-agglutination.

If tests for iso-agglutination are carried out at 37°C., it is necessary first to inactivate the grouping sera by heating to 55°C. for half an hour, otherwise the occurrence of hæmolysis may obscure a positive iso-agglutination (Schiff).

A special form of non-specific agglutination is sometimes observed with blood cells which have been preserved too long. These positive reactions, termed the Hübener-Thomsen phenomenon, are due in many cases to bacterial contamination, and this peculiarity may be conveyed by inoculation to a blood previously reacting normally. In working with old specimens, it is therefore necessary to guard against the Hübener-Thomsen phenomenon. This is particularly important in the application of grouping tests to the forensic examination of bloodstains. This form of auto-agglutination also occurs only at refrigerator temperatures, and if there is any reason to suspect bacterial contamination, the blood grouping tests should be carried out at 37°C.

To exclude this phenomenon, a control of the cells under examination may be set up with serum of group AB, best with several such sera. These sera, being those of universal recipients, will, as regards true iso-agglutination, react negatively with the cells of all four groups. Consequently, if a positive agglutination reaction is obtained in this control, the presence of the Hübener-Thomsen phenomenon may be inferred.

As regards the case reported above, there was no possibility of the occurrence of the Hübener-Thomsen reaction as we were working with fresh material. This and other types of auto-agglutination could also be excluded as we were working in Calcutta in the hot month of September. There remains the possibility of pseudo-agglutination.

Although certain workers use test tube methods in preference to slide techniques on account of the somewhat greater tendency to non-specific results with the latter, it appears to us most improbable that the anomalous results described above were errors dependent on technique. The blood grouping method employed by us is a thoroughly tested slide technique, the grouping sera used were fully controlled, yielding negative reactions where they should, as well as positive reactions where they should. Moreover at room temperature the serum of the patient produced with her own cells—as would of course be expected—no agglutination whatever. Lastly, the results of the various absorption experiments described above appear very strongly to suggest

that the unusual reactions of this patient's serum were not non-specific in origin.

We desire to thank Mr. Ahmed, Honorary Surgeon, Eye Infirmary, Medical College Hospital, Calcutta, for the opportunity of examining this blood. In the preparation of the latter part of this paper we also desire to express our indebtedness to the monographs of Landsteiner, Lattes and Schiff quoted below.

THE SURGERY OF TUBERCULOSIS OF THE ILEO-CÆCAL REGION.

By CAPTAIN K. S. NIGAM, B.S., M.D., D.T.M.,
F.R.C.S. (Edin.),

Reader in Surgery, Lucknow University.

It is an undeniable fact that the abdominal diseases of the ileo-cæcal region repeatedly claim the attention of the surgeon. The excuse for a short note on this subject is the great and possibly growing frequency of such diseases in the population around us at the present time.

The following figures show the incidence of tuberculosis in the United Provinces, taken from the annual reports of the Inspector-General of Civil Hospitals, United Provinces, and based on the statistics obtained from the Government hospitals and state aided dispensaries, etc.

Year.	T. B. Lungs.	Deaths.	Other tuberculous diseases.	Deaths.
1923	10,329	232	7,058	93
1924	11,864	307	8,739	110
1925	11,478	266	10,012	107
1926	12,912	272	10,860	97
1927	14,994	271	12,112	120

These figures may at best be taken as roughly proportional to the growing incidence of such diseases. They deal with but a fraction of the total number of such patients, and only with those who apply for relief at such hospitals and are diagnosed to be suffering from tuberculosis.

During this quinquennium it will be noticed that the rise in "other tuberculous diseases" has been one and a half times more than that of the pulmonary type. While some of the increased

incidence is attributable to more accurate diagnosis by greater laboratory and X-ray facilities than were available formerly, yet there is unquestionably a rise in the absolute and total incidence of the disease. No separate statistics for abdominal tuberculosis are available, and any such worked out from individual hospital records would not be helpful owing to multifarious statistical fallacies creeping in. The current surgical literature does not give an active interchange of views on this subject among the numerous workers in the field of abdominal surgery.

The following are brief clinical notes on a few of the cases referred for surgical treatment during the last few months:—

Case 1.—K. B., 35 years old, male. Complained of pain in the abdomen, called by patient gas pains for five years at weekly intervals, lasting a maximum period of 10 hours; gurgling in the lower abdomen. No abnormal temperature; pulse 72 to 80 p. m. No definite lump or swelling palpable; discomfort on deep pressure in the right iliac fossa. Rectal examination, no abnormality detected.

Laparotomy:—Cæcum and appendix normal. Terminal portion of the ileum for a distance of about 9 inches thickened, congested and leathery; distinctly enlarged glands in the root of the mesentery; one excised and sectioned, found typically tuberculous. Ileo-colostomy performed. After a week complete relief from pain and could take ordinary food which had been denied to him for years. Left hospital after five weeks later, having no complaint.

Case 2.—K. S., 35 years, male. Colicky pains for 2 years on and off after meals or in his own expression at "digestion time" (stated by patient to be 5 or 6 hours after meals). Lump felt in the right iliac fossa for the last six months. Pain persistent. No abnormal temperature; pulse between 76 and 90 p. m.

Physical examination showed a diffuse resistance in the right iliac region; a deep and ill defined round lump on palpation; size 3½ inches in diameter; slightly movable from side to side; tympanitic on percussion; rectal examination nothing abnormal. Total leucocyte count 9,600 per c.mm.

Abdominal section revealed a thickened and fibrotic cæcum, the thickening and congestion continued along the ascending colon for about 2½ inches, a few small lymphatic glands along its antero-medial surface. The terminal ileum had two transversely situated patches of tuberculous peritonitis, about 6 and 9 inches from the ileo-cæcal junction, indicating tuberculous ulcers in the gut underneath. Lateral anastomosis between ileum and proximal part of the transverse colon was performed with relief of local symptoms immediately after the operation. Patient left hospital in three weeks, stating that he had no trouble.

Case 3.—R., female, 25 years. Pain in the right side of the abdomen for one year. Fever, marked in the evenings, for three months. Patients suffered from fever lasting for five months after the birth of a child two years previously. Four months previously a lump developed in the right iliac fossa. Bowels acting irregularly; no diarrhoea, no vomiting, or nausea. Blood examination—no leucocytosis, no abnormality in the differential white count.

Local examination—a nodulated round lump in size about 4 inches in diameter was felt in the right iliac and lower right lumbar region. Not movable; percussion note tympanitic. No note available of the result of rectal or vaginal examination, but as far as remembered no lump or tenderness was felt.

Laparotomy revealed a thickened and adherent cæcum with diffuse scattering of small tuberculous lymphatic glands in the mesentery. Ileo-colostomy done, followed by immediate relief, a small lump could only be slightly

felt in the right iliac fossa four weeks later when the patient left hospital, expressing herself free from any complaint.

Case 4.—R. D., female, aged 20 years. Childbirth 5 months previously followed by fever daily for 4 to 5 weeks, aggravated during attacks of pain in the abdomen; subsequently she used to get attacks of pain in the abdomen with vomiting (once or twice) and fever lasting not more than 24 hours simulating in history recurrent appendicitis.

Duration 3 years.

Indigestion, no appetite, diffuse pain in the abdomen after meals and also in turning to the left in bed.

Total leucocyte count, 12,500 per c.mm., differential count nothing abnormal (no relative or absolute lymphocytosis).

Local examination detected a large nodulated lump in the ileo-cæcal region, slightly movable but very tender. Rectally, definite tenderness present towards the right side in the pelvis. Uterus freely movable.

Laparotomy:—A thickened cæcum was found with obvious tuberculous glands matted together along its medial side, but none in the mesentery. The terminal ileum for about 4 inches dilated and thickened to about three times the size of gut immediately proximal to it. Uterus and its adnexa normal. An attempt was started to remove the whole mass (considering that no diffuse scattering of tuberculous glands in the root of mesentery was visible to the naked eye), but the blood-pressure was at this time reported to be very low. Hence rapid closure of the abdomen was undertaken. The patient gradually sank and died the same evening in spite of routine attempts to pull her through with exhibition of stimulants and intravenous administration of glucose, gum acacia, saline, etc.

Case 5.—R. K., aged 20 years. Married, but no issue. Gurgling with pain in the abdomen. Duration 8 months. Lump palpable in the right iliac fossa, very tender, not movable. Laparotomy revealed the terminal 6 inches of the ileum thickened and congested, the cæcum, appendix and the region of the ileo-cæcal junction was one matted mass with obvious tuberculous glands; one gland removed and its tuberculous nature identified then and there by foci of caseation in it. Ileocolostomy followed by marked relief, pain vanished, appetite regained. Left hospital happy after three weeks. Lump still felt in the ileo-cæcal region but no tenderness.

Case 6.—M. B. L., male, Hindu, aged 45 years. Disease of ten years duration, at first occasional attacks of colicky pain with intervals of six weeks or so. Later the intervals grew shorter. He said that for the last five years he had had attacks of pain nearly every week, each lasting 8 to 10 hours. He got his abdomen massaged 4 years before by someone who noticed for the first time a lump in the right iliac fossa. He suffers from constipation. Temperature about normal. Pulse 82 p. m. Laparotomy revealed matted and enlarged glands, pressing distinctly on the ileo-cæcal junction. The cæcum itself was thick, tough and fixed. The terminal 6 inches or so of the ileum revealed three patches (situated within 2 inches of each other) of peritonitis with evident miliary tubercles on them, indicating tuberculous ulcers inside. Ileocolostomy done, followed by remarkable relief. He left the hospital relieved.

Case 7.—G. M. U., Mohammedan, male, 40 years. Treated for several weeks as a case of suspected typhoid fever, ending in acute, intestinal obstruction. When patient was received for surgical aid he was acutely ill. Absolute constipation, regurgitant faecal vomiting and diffuse abdominal tenderness marked by tympanites were noted.

Laparotomy, done under local anaesthesia, revealed extensive tuberculous adhesive peritonitis. Blood stained peritoneal fluid with *B. coli* odour. Interlacing adhesions with extreme distension of the upper jejunum compelled the performance of jejunostomy. The patient rallied and improved remarkably, the faecal fistula closing by itself. After about three months he developed severe diarrhoea and died.

Case 8.—Q. A., male, 50 years, married with children, non-vegetarian, occupation nil for about ten years, leading a retired life supported by sons, body well nourished.

Complained of:—(1) Pain and distension of abdomen. (2) Inability to pass faeces or flatus for 2 days before admission. (3) Regurgitant faecal vomiting.

Patient was questioned scarchingly about any gastrointestinal disorder preceding present complaint immediately or more remote. He most emphatically stated (corroborated by his relative) that so far as his abdomen was concerned he had never experienced anything wrong about it. He claimed to have lived a perfectly healthy life, never affected by any trouble about digestion or pain in abdomen. Many such patients give no definite information about their antecedents, being poor observers, but his firm denial suggested insignificance of any discomfort occasioned by his abdominal condition previous to the present emergency.

Physical Examination.—Except for marked tympanites and distension, most marked in the middle of abdomen, feeble peristaltic gurgles heard on auscultation, nothing more of note could be elicited. External hernial regions unaffected. Rectal examination negative. Temperature 98°F. Pulse 132 p. m.

Treatment.—Exhibition of atropine, high rectal enema repeated half hourly and once done under chloroform with negative result.

Operation.—All cases of acute abdomen, provided they or their relations do not altogether refuse it, are given the desperate chance of an operation. The above patient was operated under novocain-adrenalin infiltration anaesthesia. (His stomach was washed out previously.) As soon as the peritonium was opened it was found in an advanced state of miliary tuberculosis with the bowels matted. The abdomen was closed promptly with a tube tied into the most prominent coil of jejunum to relieve obstruction.

Note:—The last two cases were not of ileo-cæcal tuberculous but serve to illustrate tuberculous peritonitis cases met with in surgical practice.

The characteristic feature common in the clinical picture of all the above cases was pain in the abdomen.

Nature of this pain.—It comes on spontaneously, and is more or less intermittent, sometimes with an interval of days in the beginning, appearing immediately after meals or 5 or 6 hours after meals, is partially relieved by local pressure, escape of flatus or the passage of a motion; the nature of the pain is described variously as colicky, twisting, or gas pains. The duration varies from a few hours to 2 hours at a time, severe enough to make the patient take to bed and groan during its continuance. In one case the pain was aggravated on turning to the left side. The severity of the pain is only temporarily relieved by fomentations or enemata.

Local examination reveals some abnormality in the right iliac fossa. The abdominal wall movements in the right iliac region are comparatively sluggish. Pain and tenderness are present, deep palpation reveals either a nodular or glandular lump or an ill-defined swelling, or only a peculiar gurgle. This latter gurgle is of doubtful value though in all doubtful cases where the diagnosis of abdominal tuberculosis was established on the operation table this doubtful gurgle was made out by pressure over right iliac fossa in the previous history of the case. The same is also made out in undoubted cases of chronic appendicitis,

disease of the cæcum, entero-spasm, or even in the normal individual.

Among other signs and symptoms, loss of body-weight is suggestive if the patient is seen by a careful observer, diminished appetite is fairly common, nausea and vomiting are conspicuous by their absence. Distension of the abdomen is inconstant, and visible peristalsis has been noticed but rarely. The total leucocyte count varies between 6,000 and 10,000, with no marked cellular deviation from the normal ratio. It is not unknown for the abdomen to have been opened for some supposed mesenteric cyst or other lesion, when diffused or localised tuberculosis, peritonitis or tuberculous lymphadenitis or ulcerative tuberculous ileo-colitis has been revealed. Fever and an increased pulse rate are not present with any regularity or constancy sufficient to form an essential part of the clinical picture of such cases.

Having found a tuberculous abdomen, when least suspecting it, after laparotomy one is inclined to keep its probability prominently before oneself, when face to face with abdominal cases either complaining of chronic intermittent pain or lumps in the lower umbilical, right lower lumbar, and right iliac regions.

The comparatively younger age of the patient points to tuberculosis; after 45 or 50 such symptoms suggest malignancy. Pain in malignant disease or the ascending colon or cæcum is more constant, and cachexia becomes marked early. In malignant disease the lumps (glandular—of course late in the course of disease) are characteristically hard to feel. Diarrhoea alternating with constipation has been met with both in tuberculous and malignant disease. Rectal digital examination reveals in the majority of cases nothing in particular. A sense of vague discomfort which the majority of patients describe is of no help. Skiagraphy after a bismuth meal or opaque enemata, carried out in two other cases showed nothing characteristic in tuberculous cases, though, if utilised in all cases, it might prove of some value. The peritoneal effusion of fluid does not help as it occurs late in cancer, when the diagnosis becomes otherwise obvious by palpation of metastatic growths. In none of the above tuberculosis cases was any free fluid found.

Although in comparatively early cases the operative procedure may be decided upon beforehand, usually a surgeon has to determine the exact line of action after the abdomen has been opened. Then one of the following three pictures is most commonly met with.

(1) Diffuse tuberculous peritonitis or miliary tuberculosis of the peritoneum, with or without extensive adhesions in the ileo-cæcal region.

(2) An irregular fibro-fatty mass in the ileo-cæcal region involving the cæcum and variable lengths of the ileum and ascending colon:—hypertrophic (really pseudo-hypertrophic) ileo-cæcal tuberculosis.

(3) The terminal 4 inches to 6 inches of the ileum is found thickened and dilated. Externally it has a dull red colour, with or without depressed and scarred patches showing a few miliary tubercles on the peritoneal aspect, indicating ulcers situated on the corresponding mucous surface of the bowel.

This condition obtains in the adjoining cæcum for a variable distance, usually not in the whole of it. This condition has been more frequently met by us and is a combination of both forms of tuberculosis: "hypertrophic cæcal tuberculosis" and "ulcerative entero-colitis," though in our cases it was the termination of the ileum that was (pseudo) hypertrophied and also in some cases ulcerated.

In both types 2 and 3 glands varying in size and number were found affected in the ileo-cæcal angle and adjoining mesentery.

Treatment.—As the majority of our patients arrived in hospital in a very low state of vitality, they were treated by ileo-colostomy (with safeguards against causing intestinal obstruction). It was rapidly performed and the patient experienced very little shock and almost invariably a happy patient in bed was encountered the very next morning after the operation, and he or she remained so till discharged from the hospital.

In two other patients followed up for one year after operation, were found to be enjoying good health. It is exceedingly difficult to trace patients after discharge and to follow up their clinical history afterwards.

Excision of the cæcum is the operation of choice in the hypertrophic form if the disease be localised. The diffuse tuberculous involvement, including several inches of the ileum and matted up glands, combined with the low general condition, induced the decision to perform the comparatively mild operation of ileo-colostomy, with relief of symptoms.

Simple opening of the abdomen in tuberculous cases is accredited and known sometimes to be followed by considerable improvement. Oxygenation of the peritoneum is an added advantage. Rest is given to the affected bowel by the short circuiting operation of ileo-colostomy. If any large lumps of glands are noticed they may be removed with ease. The well known principles of treating tuberculosis patients in general, e.g., rest, fresh air, sunlight, good food, and tonics like calcium are adopted in treatment, in conjunction with the above surgical measures, to try to break the vicious circle of disease.

CONCLUSIONS.

1. There is at present a growing incidence of non-pulmonary forms of tuberculosis in the United Provinces.

2. Some cases clinically suggesting localised hypertrophic cæcal tuberculosis (tuberculoma of the cæcum) on opening the abdomen revealed tuberculous ulcerative lesions more or less well marked in or limited to termination of the ileum.

3. Patients present themselves late for surgical aid.

4. The milder operation of ileo-colostomy is attended with less shock than is excision of the cæcum, is perfectly well borne with relief, but the number of cases cited is too small to establish any standard method of relief.

5. The frequency of tuberculosis of the abdomen is to be kept in mind in dealing with doubtful abdominal conditions, acute or chronic.

CARDIOSPASM.

By NISA NATH GHOSH, M.B.,

Teacher and Radiologist, Berry White Medical School, Dibrugarh, Assam.

"CARDIOSPASM" is a rare condition of the œsophagus, giving rise to its dilatation and to projectile regurgitant vomiting in many cases, and to dysphagia as well, in a few.

Synonyms.—There are numerous terms used for this condition—viz., cardiospasm, hiatal œsophagismus, functional hiatal stenosis, pre-ventriculosis, phrenospasm, etc. The one most commonly used is "cardiospasm." But unfortunately this is a misnomer. For (1) firstly, it is doubtful if there is true spasm at all in this disease; (2) secondly, the site of obstruction or spasm—whatever we may call it—is not at the cardia, but well above it, in the thoracic portion of the œsophagus; and (3) lastly, extensive dilatation of the thoracic portion of the œsophagus is a more marked feature of this disease than spasm.

Further "spasm at the cardia" and "cardiospasm" are two quite distinct conditions. In "spasm at the cardia" there is temporary and transient obstruction. In "cardiospasm" there is more prolonged obstruction and along with it diffuse dilatation. In spite of these differences there exists an inter-relationship between the two. Most observers consider spasm at the cardia as an early condition often preceding and frequently ending in the more chronic condition of cardiospasm.

How is cardiospasm brought about? To understand this we must recall to mind a few physiological facts. Normally swallowing is a reflex act all throughout, except at the very beginning, when it is voluntary. The onward passage of a bolus of food through the œsophagus is brought about by the harmonious working of two sets of impulses—(1) one set passing along the vagus and causing contraction of the œsophageal musculature just above the bolus; and (2) another the inhibitory set passing along the sympathetic and causing relaxation of the œsophageal muscles below the bolus. The cardia and the portion of the œsophagus at the diaphragmatic opening are no exceptions and are influenced in the same manner as the rest of the gullet.

The mechanism of its production.—If a man with a full stomach is turned head downward

and heel upwards, he does not regurgitate his food. This as Dr. Jackson suggests is prevented by the "pinchcock" action of the diaphragm and the kinking of the abdominal portion of the œsophagus. This "pinchcock" opens on the approach of a bolus of food in normal swallowing, which is a reflex act except at the very beginning as already stated before. The late Sir William Osler believed that the so-called spasm in cardiospasm is nothing but the failure of the "pinchcock" to open on the approach of a bolus of food—i.e., a dissociation of the normal reflex mechanism of swallowing. Dr. McCrae is of opinion that all cases studied by Dr. Jackson and Dr. Clerf had obstruction at the diaphragmatic opening and not at the cardia. This opinion suggests two things—(1) that the site of the trouble is not at the cardia but above it, (2) that the "pinchcock" action of the diaphragm may play a part in the production of the so-called spasm.

Signs, symptoms and diagnosis.—The trouble complained of by patients may be a certain

amount of dysphagia for both solids and liquids in some cases, and projectile regurgitant vomiting.

The diagnostic features are:—(1) dysphagia more or less; (2) projectile regurgitant vomiting; (3) absence of hydrochloric acid and pepsin, blood and tissue fragments in the vomited matter; (4) absence of the second sound of swallowing on auscultation over the interval between the xiphoid and the left costal arch; (5) absence of pain and enlargement of cervical lymph glands; (6) the characteristic X-ray

picture after an opaque meal showing well marked dilatation of the œsophagus with a conical lower end, without any irregularity but with well defined and regular margins.

Illustrative case and radiogram.—These radiographic features as well as the fact that the seat of the spasm is well above the cardia were well seen in a case of cardiospasm which came to my notice some time ago. The radiogram of this case unfortunately got spoiled and spotted, so I had to get a drawing made of the radiogram. This drawing clearly shows the above mentioned features. A short note about the case is as follows:—

A patient, Aftabuddin, Mahomedan male, aged 22 years, came under my observation on 1st May, 1928, for dysphagia. The diagnosis was settled by X-rays which is the surest means of diagnosis nowadays in such cases. He was treated with bromides and atropine and finally discharged relieved on 16th May, 1928.

My best thanks are due to my students Sj. Krishna Kamal Bhowmick and Sj. Ratneswar Bhuyan, for the excellent black and white drawing they have made of the accidentally spoilt radiogram of the case.

EXPERIMENTS ON THE VITAMIN B (ANTI-NEURITIC FACTOR) IN PARCHED RICE; ON HONEY; AND THE MUCOUS SECRETION OF THE PIGEON'S MOUTH.

By S. N. MATHUR, M.B., B.S.,

Lecturer in Physiology, King George's Medical College, Lucknow.

1. *Parched Rice.*—Some time ago, the author—(Mathur, 1928)—showed the superiority of parching over that of boiling rice so far as digestibility is concerned. The present observations show in addition that parching is not inimical to the anti-neuritic factor, vitamin B.

The experiments were carried out on pigeons. One batch was fed on polished rice, and the other on bazaar purchased parched grain (one set on *parmal*, and the other on *kheel*). Those which were fed on polished rice showed definite signs of polyneuritis in the third week, whereas there was no indication of it in the others, even after 46 days. Fig. 1 shows the appearance of one of these latter sets of pigeons on the last day of the experiment.

2. *Honey.*—Honey, as is well known, is held in considerable popular esteem for its health-promoting qualities. If this popular belief be true, it cannot be because honey contains any anti-neuritic vitamin. Pigeons fed on a diet of polished rice and honey developed polyneuritis even 3 or 4 days earlier than the controls fed on polished rice alone. These honey-fed pigeons

also were more lethargical, and suffered more severely from diarrhœa than the controls. This diarrhœa ceased some 36 hours before death,

Fig. 1.

and was replaced by severe vomiting of a green coloured semi-fluid material.

At post-mortem there was found marked anæmia of the brain and spinal cord, and deep congestion of the abdominal organs. A very peculiar feature which was found regularly was an atrophy of the last three inches of the intestine, sharply demarcated from the neighbouring congested part.

3. *The Mucous Secretion of the Pigeon's Mouth.*—During the course of one of the above experiments, it was noticed that a young pigeon which was being fed by its parent on polished rice did not develop neuritis, whereas the other pigeon of the same brood which was feeding itself developed neuritis. This appeared to indicate some beneficial effect resulting from feeding by the parent. Accordingly, two young pigeons were taken from the same nest, and when they were able to feed themselves, one was isolated and allowed to feed itself, the other was isolated, given no opportunity to pick food, and continued to be fed on polished rice by its parent. The parent died on the 26th day, but the young pigeon remained well, and was then allowed to feed itself. Its nest mate, on the other hand, developed polyneuritis and was very ill at a time when the other bird seemed in full, vigorous health. Fig. 2 shows the difference at this stage between the two birds. The one on the left was fed by its parent.

Fig. 2.

SUMMARY AND CONCLUSIONS.

1. Parched rice still contains a sufficient supply of the anti-neuritic factor.

2. Honey does not contain any anti-neuritic factor; it rather hastens the appearance of polyneuritis in pigeons.

3. Pigeons fed by their parents are more resistant to lack of the anti-neuritic factor than are pigeons separated from their parents immediately they are able to feed themselves.

In conclusion, I have to acknowledge my grateful thanks to Dr. W. Burridge for his invaluable advice, suggestions, and criticism.

VOLVULUS OF THE SMALL INTESTINE.

By R. C. McWATTERS, M.B. (Lond.), F.R.C.S. (Eng.),

LIEUTENANT-COLONEL, I.M.S.,

Principal, Medical School, Agra.

In Europe volvulus of the small intestine is a comparative rarity, but in India it is quite a common variety of obstruction. The writer has found it in nearly one-third of all cases operated on or examined post-mortem, and has heard other surgeons practising in India remark on its frequency. In a recent article in the *Indian Medical Gazette* Captain Ghosh(1) of the Darbhanga Medical School referred to it as the commonest variety of obstruction seen there.

observed an area of dullness towards the right side of the lower abdomen, corresponding to coils of affected intestine distended with fluid, as found at operation.

In contrast with cases reported in England the extent of bowel affected is usually considerable, sometimes the greater part of the small intestine; the lower limit is nearly always but a few inches above the ileo-cæcal junction. The severity of the torsion varies greatly; in a few cases congestion may be extreme and gangrene present, but more commonly congestion is slight, and hardly greater than in other forms of obstruction, the twist being enough to obstruct the bowel without greatly interfering with the circulation.

On first opening the abdomen one will find the blood stained exudate and congested bowel characteristic of volvulus in the more severe cases, but not in all.

In a large volvulus of the usual left to right variety on inserting two fingers one can generally detect a thick tense band of mesentery a little to the right of the middle line. This is the pedicle of the volvulus, and a finger may be passed round its left free edge and hooked behind it. When the parts are fully exposed, the cæcum and the lowest part of the small intestine are found to be empty, and if a finger is made to follow the empty coil upwards it winds round the left edge of the twisted mesentery and is lost to sight. In the milder cases the parts are so loose that it is difficult to believe that one is really dealing with a volvulus. But on tracing

Diagrammatic Representation of the formation of pedicle with small intestine winding round its free edge.

These cases have no distinctive symptomatology by which they can be distinguished from other cases of small intestine obstruction. A history of eating some coarse indigestible food such as gram, or of straining at work at stool is common; the onset is usually sudden and the pain very severe. The writer has sometimes

the empty bowel upwards it is found to be continuous with the distended bowel above, and on rotating the whole mass in a clockwise direction the empty ileum and cæcum fill. This and the ultimate recovery of the patient, which usually follows in this type of case, is a satisfactory confirmation of the diagnosis, but unless the

nature of the obstruction is recognized by the foregoing manipulations it is quite possible to reduce the volvulus without knowing it, and to waste valuable time in searching for an obstruction which no longer exists. It may be that the cases one sometimes hears of in which no organic obstruction could be found at operation may be of this nature.

One might suppose that spontaneous reduction might occur in some of these cases, and the writer has published two cases in which there was the strongest evidence that this had happened. In one the patient died of collapse shortly after the bowels had been opened, and bruising and ecchymosis was found in the bowel and mesentery with such a distribution that a recent volvulus was the only possible explanation. In another case the patient had a stricture of the intestine.

The small intestine was scarred and adherent to the mesentery in just such a manner as would result from a previous volvulus and there was a history of a previous attack of obstruction corresponding with this. This scar had contracted until a stricture was produced.

Treves(3) remarks that the twist is sometimes very slight, only half a turn, and that at post-mortem when the contents of the affected bowel were allowed to escape and the distension relieved the obstruction in one case disappeared.

In Europe recovery from acute obstruction (which is not merely an episode in a case of chronic obstruction) is extremely rare apart from operation. But in India, if the many cases which refuse operation are treated with repeated high enemata, a surprisingly large proportion—perhaps one in eight—will be relieved, sometimes not until as many as four enemata have been given. It is difficult to imagine what has happened in such cases, but if it be conceded that volvulus of the small intestine is common in India, and that it is specially favourable for spontaneous reduction, we have an explanation to hand for some at least of them.

FRAMBOESIA TROPICA IN BENGAL.

By B. C. MUKHARJI, M.B., D.P.H.,

Bengal Public Health Department.

A DISEASE locally known as *myang* was reported for the first time in February 1927 by Babu Rebat Mohan Dutta, M.A., Subdivisional Officer of Rangarh, to be spreading among the hill tribes of his subdivision. Mr. C. G. B. Stevens, I.C.S., Deputy Commissioner of the

Chittagong Hill Tracts, reported the extreme prevalence of the disease at Rangarh on the Feni river and requested the Director of Public Health in August 1927 to carry out investigation and treatment. The late Dr. L. M. Ray, then Civil Surgeon at Rangamati, and myself, then Officiating Assistant Director of Public Health, Dacca and Rajshahi circles, investigated the disease in September 1927 and reported that the disease was yaws (frambœsia).

The disease is characterised by two stages; (1) the stage of primary lesions and (2) the stage of secondary granulomatous eruptions. The disease is prevalent mostly during the rainy season. In winter in some cases it runs a latent course, only to reappear in the following wet weather. The disease runs an indolent course from one to four or five years. Spontaneous recovery has been recorded after a prolonged period of suffering. So it seems that immunity from the disease develops very slowly. The primary lesions may appear as an ulcer or as a papule, which soon breaks into an ulcer. Primary ulcers have been found on the genitalia but they may be extra-genital. (During the investigation female patients were not thoroughly examined as there was no nurse attached to the dispensary to attend the patients). About three months after the appearance of the primary ulcers, which have not the characteristic hard feeling of a Hunterian chancre, there is a feeling of malaise and rheumatoid pains in the joints. The pains precede characteristic eruptions on the skin. The pains may be so severe as to confine the patient to the bed. There is no arthritis. The pains subside on the appearance of eruptions. The papules appear on the skin and break down, forming ulcers with clean-cut edges and granulating bases. In some cases the papules grow into small warty tumours which break down and form unhealthy looking weeping ulcers with clean cut edges. Ulcers of the size double that of a rupee have been found in some cases. The neighbouring lymph glands become enlarged, but like syphilitic glands have never been known to suppurate. Bilateral enlargement of the inguinal glands was found (in the patient Iswar Chandra, Tippera). The ulcers run a prolonged course and on healing leave pigmented patches. The eruptions do not come out in one crop. Warty growths appear in succession one after another. Joint pains are generally not present when these supplementary growths appear. Warty growths have been noticed in the anus. The skin eruptions have no selective distribution. There is no involvement of the internal organs. In only one case (Iza Ram Das) necrosis of the nasal bone and falling of the bridge was noticed. The patient denied a history of syphilis. It is still very doubtful if the necrosis of the nasal bone in this case was really due to yaws. Possibly it was the result of a previous syphilitic infection. Dr. Tarananda Mukharji, M.B., D.P.H., then District Health Officer of Chittagong, supplied

the following blood picture of *myang* disease (yaws):—

	Per cent.
Polymorphonuclear leucocytes ..	56
Lymphocytes ..	37
Large mononuclear leucocytes ..	5
Eosinophiles	2

Treponema pertenue has been reported to be the causal agent in these cases. The disease is spread by local infection by contact and through dirty habits.

The disease can be differentiated from syphilis by the following points:—

(1) The chancre or primary ulcer lasts much longer than that in the case of syphilis.

(2) In the prodromal stage of secondary eruptions on the skin, there is articular pain and absence of fever.

(3) Subsidence of the joint pains when the eruptions on the skin appear.

(4) The nature of the eruptions on the skin.

(5) Absence of involvement of the internal organs. The disease is mostly located in the skin.

(6) Congenital propagation of the disease has not been traced (among the cases investigated).

The incidence of the disease in a few villages and its position in 1927 was worked out by me, and was as follows:—

Mr. A. S. Hands, I.C.S., Deputy Commissioner, Chittagong Hill Tracts, reported in November 1928 that the results obtained last year were so satisfactory that the deputation of a touring Sub-Assistant Surgeon for the next three months might result in stamping out the disease. The Civil Surgeon has since reported that the prevalence of the disease has comparatively subsided and only a few cases now come occasionally to the Ramgarh and Manickcherry dispensaries.

Spread of the disease.—The disease is prevalent in the Ramgarh subdivision and also in the Tippera Raj Estate. It first appeared in the area about fifteen years ago when an elephant trap (*khedda*) was constructed by the estate. The trap was maintained for a long time and it is believed that the Magh people from Burma and the people from the Lushai Hills were present among the labourers. It was then that yaws (locally known as *myang* or elephant disease—so called from its association with the elephant trap) was noticed among the people for the first time. So it seems that yaws was imported into the area from Burma by people coming from yaws-affected districts in Burma. Yaws is widely prevalent in the Chin Hills in Burma and in the Assam Valley. It has also been reported by Dr. Ramsay to be prevalent among the hill tribes of Cachar. Dr. Muir has recently discovered the same disease in Bengal, on the Birbhum border line. Dr. Ramsay contends that yaws was first introduced into Assam from Burma via the hill tracts and it has now

Neosalvarsan effects a speedy cure. One injection of this remedy or similar derivatives is often sufficient to heal the ulcers, but relapse of joint pains has been recorded after one injection of neosalvarsan. Further investigations are necessary to ascertain the exact dosage of the remedy that would effect a permanent cure. Seventy-one cases were treated by me during the course of my investigation. The Sub-Assistant Surgeon of the Ramgarh dispensary treated cases coming to the dispensary. A Sub-Assistant Surgeon was then deputed to carry on the treatment of the disease, and 673 patients were treated in 1928 with the specific remedies.

spread to the Bengal-Bihar border line. The same disease was traced by Dr. Tarananda Mukharji, M.B., D.P.H., in March 1928 to have penetrated into villages in the extreme north of the Chittagong district, and he thought that the disease had spread from the hill tracts to the villages of Chikomia, Barabit, Koila, Adharia, and Datma in the Fatikcherry police station of the Chittagong district.

All District Health Officers should keep an eye on the appearance of the disease in their respective areas and should report to the Director of Public Health the first case that they come across.

* THE FOOD VALUE OF THE NUT OF
ANACARDIUM OCCIDENTALE (HIJLI
BADAM).

By N. K. CHATTERJEE, B.Sc.,

Assistant Analyst, Public Health Laboratory, Bengal.

Hijli nut (Cashew nut of Bengal) or *Hijli Badam* of Hijli, Midnapur, generally known as *Kaju* on the east and west coasts of India, is a native of tropical South America, whence it was introduced into India by the Portuguese some time in the 17th century in their Goa territory; and even up to the present day it is nowhere so abundant as in the western coast of this country. It has, however, become thoroughly naturalized now throughout the coastal regions of India, extending from Burma to Bombay. Consequently it is also found established in the coastal sandy tracts of Hijli and Chittagong in Bengal, whence it has derived the name of *Hijli Badam*. In South and West India it is known as *Kaju*, adapted from the South American name *acajou* which by French transliteration has been rendered into Cashew nut; since then it has been in use as a nutritious food, more specially as a fatty food. In Bombay there is an extensive trade in this nut exported from Goa. The Calcutta market is also supplied from South India. Sir George Watt(1) says that the kernels are so extensively eaten that unless more nut is produced it is almost impossible to manufacture sufficient oil for any trade purpose. He recommends the extension of its cultivation on the ground that it will form a supplementary staple food. Dymock(2) suggests that the coastal forest region and barren sandy tracts can be utilized for its cultivation with little or no difficulty. Recently a correspondent from Hijli writes in a literary periodical about the demand for the nut, and earnestly suggests that the greatest efforts should be made to extend the cultivation of such a useful plant in the unused vast sandy tracts of the coast of Bengal, to secure an inexhaustible supply of wholesome food.

Identification.—As regards identification it cannot be confounded with *jungli badam* which is generally found in western and southern India, the seeds of which yields a large percentage of oil; this tree, *Sterculia fetida* (L)(1) belongs to the genus *Sterculia*, natural order *Sterculiaceæ*. It has not much importance as a food, but in times of scarcity the seeds are roasted and eaten like chestnuts. The tree we are dealing with, however, is *Anacardium occidentale* of Linneus(3) or the *Hijli Badam* of Bengal. It belongs to the natural order *Anacardiaceæ*, genus *Anacardium*, species *A. occidentale*.

It (Fig. 1)(4) is a tree, 20 to 30 feet high, with short crooked trunk, and the branches are quite glabrous and terete, leaves thick, coriaceous, about 4 inches to 6 inches long and $2\frac{1}{2}$ inches to 3 inches broad, obovate or elliptic, rounded at the

apex, glabrous with finely reticulated veins, the base cuneate; main nerves 10 to 12 pairs, prominent beneath, petioles short and thick, not exceeding $\frac{1}{2}$ inch in length. Flowering panicles terminal, longer than the leaves, with branches

Fig. 1.—*Anacardium occidentale*.

cymose, bracts $\frac{1}{2}$ inch to $\frac{2}{3}$ inch long, ovate, very acute-nerved, finely puberulous, on the outside; peduncles lengthening with age. Sepals $\frac{1}{2}$ inch long, lanceolate, puberulous on the outside; petals $\frac{1}{2}$ inch to $\frac{3}{4}$ inch long, linear, lanceolate, deflexed from the middle, minutely puberulous outside; stamens about 9, one longer than the other, exserted beyond the recurved petals. Ovary about $\frac{1}{2}$ inch long, glabrescent, attenuated into a subulate style $\frac{1}{4}$ inch long. Fruit (Fig. 2) kidney shaped, about 1 inch long and nearly as broad, with a thickness about $\frac{1}{2}$ inch, greyish brown, inodorous; its pedicle thickened and, on maturity, fleshy, coloured like an apple yellow and red, reaching the size of a medium sized pear(5). A native of Hijli, Bengal, it grows on the east and west coast of India. This is the only species out of six known in tropical America, which has been introduced into this country.

Limits of Cultivation.—There is no difficulty in its cultivation, neither does it cause any local disadvantage; mature seeds are simply placed under the wet sand during the rainy season; its cultivation is limited only to sandy coastal tracts, beyond which its growth is not favourable.

Economic Value.—While keeping in mind that though there is no existence of any trade in the nut at present in Bengal, owing to its production in very small quantities, quite insufficient for the

* Being a paper read at the Indian Science Congress, Madras, in January, 1929.

purpose, yet we must not forget the fact that an extensive trade in this nut is carried on in Bombay by import from Goa, the price of 1 cwt. being not less than Rs. 18. In Hijli, nuts are sold at Rs. 10 only per maund, for the outside market the price may be higher according to its demand. The weight of the kernel of each nut is from 0.9 to 1.5 gm. About 60 plants can be grown in an acre and if the least quantity of crop be 2 maunds per tree, the harvest will amount to over

The kernel of the raw nut is also used and a large percentage of oil is obtained from it. Fresh nuts show traces of anacardic acid and cardole in the kernel, the presence of which makes the kernel not so palatable as the roasted one; hence for flavour and palate the roasted nut is preferred. The nut contains all the proximate principles of food. The table given below gives the composition of the kernel of the raw and roasted nut as found from actual analysis:—

Kernel from different sources.	Water.	Protein N × 6.25	Fat.	CARBOHYDRATES.			Fibre.	Ash.
				Starch.	Soluble carbo- hydrates.			
Raw { Minimum ..	9.5	14.5	39.0	6.5	3.5	..	4.5	2.05
Maximum ..	22.0	16.25	42.5	7.4	6.5	..	6.5	3.07
Average ..	19.0	15.8	41.8	7.0	5.0	..	6.0	2.7
Bazar sample { Minimum ..	5.9	18.6	35.0	6.7	4.5	..	6.0	2.35
so-called roasted { Maximum ..	7.0	28.6	40.9	9.0	6.5	..	11.0	4.0
Average ..	6.5	23.6	40.0	8.0	5.5	..	8.5	3.17
Constituents of milk (cow)	87.53	3.18	5.27	4.32	..	0.7

120 maunds of nuts, which at Rs. 10 per maund means about Rs. 1,200. The peduncles also of the matured nut are sold as *Lanka Am*; from its sweet juice a kind of weak spirit is available

The last column, being the averages of the value of several cow milk samples, shows the percentage of food principles of milk as against those of the nut. In protein the raw and roasted samples are richer 5 and 7 times respectively; in fat they are about 8 and 7 times respectively; and in digestible carbohydrate both are 3 times richer than that of milk. The total calories per 100 grams of nut is 670.0 against 66.72 calories per 100 gms. of milk, i.e., the former is ten times higher than the latter. The mineral contents in the nut are about $4\frac{1}{2}$ times more than that of milk. The following table shows the percentage of different bases and acids in the ash of the nut against those of the milk.

	Hijli nut.	Milk(6).
K ₂ O	7.2	24.5
Na ₂ O	29.7	11.0
CaO	2.31	22.5
MgO	1.25	2.6
Fe ₂ O ₃	1.75	0.3
MnO	1.0	..
P ₂ O ₅	14.7	29.5
SO ₃	3.0	1.0
Cl	0.5	15.6
SiO ₂	3.61	..

Fig. 2.—Fruit.

which will also fetch some price. In addition to the fruits the tree yields a gum in large stalactitic pieces, tannin from the bark, and the juice by incision of the bark for dyeing net, ropes, etc.; lastly, a durable wood is available from the trunk.

Food Value.—Generally the kernels of roasted or well-dried nuts are eaten or used in confectionery.

So one pound of nut will be equivalent to 10 pounds of milk in energy value, with $\frac{1}{20}$ th part of phosphorus, about half the quantity of iron, $\frac{1}{30}$ th part of potash, $\frac{1}{3}$ rd of soda. The kernels of the nut are mostly used in the preparation of vegetable curry, and Indian sweetmeats and cakes, like other food-stuffs containing fat, such as ground nut, almond and walnut for making the preparation more tasty. The nut is a food

of the fatty group and compares favourably with such foods as ground nut, almond, walnut, etc. The comparison is as follows:—

mentioned in Sir George Watt's *Dictionary of Economic Products* that the finest oil is superior to olive oil and the equal in every respect to

	HIJLI NUT.		GROUND NUT(7).		Almond, dried.	Walnut kernel as sold in the market.
	Raw.	Roasted as sold in the market.	Raw.	Fried.		
Moisture ..	19.0	5.35	26.13	4.2	5.4	4.6
Protein ..	15.35	23.6	26.13	24.2	24.2	15.6
Fats ..	41.0	40.0	43.81	47.2	53.7	62.6
Carbohydrates ..	12.0	13.5	13.68	8.0	7.2	7.4
Ash ..	2.56	3.17	1.58	..	2.9	2.9

It is almost as nutritious as ground nut, almonds and walnut, except for being a little inferior to them in fat value, but in digestible carbohydrate and mineral matter it is superior.

In Fig. 3 a photograph of the starch found in the nut flour is given; the characteristics of the granules being that they are irregular in size with

almond oil. From the nature of the oil it is not inferior to ground nut and mohua oil as a substitute for ghee or as an adulterant of the latter. Also it may be used as a substitute for almond oil if a fine preparation is made. The comparative figures of chemical analysis of oils are given below.

Oil.	Sap value.	Iodine value.	R. W. value.	Butter Ref. Reading.	Specific gravity.	INSOLUBLE FREE FATTY ACID.	
						Titre test.	Melting point.
Hijli nut ..	188—192	81—88	0.5—0.9	53—55	0.918	31.5	36.5—37.5
Ground nut ..	185—195	85—94	—	54—56	0.917	30.5	36.0
Mohua ..	186—194	58—64	1.6—1.7	50.5	—	—	—

a diameter 3.4 to 9.0 μ , with no concentric rings, oval, having elongated hila at the centre, lengthwise a little bent. The most important nutrient in the nut, however, is the oil from its kernel. It is a yellow bland oil, but when the oil is pressed

Fig. 3.—Starch Granules of Hijli Nut Flour.

out of a machine it becomes brownish yellow, probably on account of the kernels not being thoroughly cleaned off their testas. It is

The oil congeals below 10°C.; with sulphuric acid without agitation a brown ring forms between, but after mixing it becomes a thick red mixture; with cold nitric acid it becomes a hazy deep orange colour; when heated with acid the orange colour deepens. Bellier's test gives a positive reaction for this oil (the temperature at which turbidity occurs being about 25°C.) which shows the presence of arachidic acid in the oil. The action of bromine on the thin film of oil has been examined; the bromine value has also been directly estimated, and is 53 to 55. The characteristic of the brominated film is seen under the microscope.

The film (Fig. 4), as shown, is slightly wrinkled with translucent droplets. To the naked eye it is soft, sticky, but often tends to run into streaks and lakes rather than to remain even.

Oil from the pericarp is thick, dark brown, having a specific gravity of 1.014 (Lepine), it chiefly contains cardole and anacardic acid. The oil is recommended as an external application in leprosy, ringworm, corns, and obstinate ulcers. It is powerfully rubescent, vesicant and an insecticide and requires to be used with caution.

Influence on Nutrition.—Feeding experiments on rats have been started some time ago with a view to gauging its nutritive value. Satisfactory results are being obtained. Young rats are growing as usual on an exclusive *Hijli* nut diet, both raw and roasted. They appeared quite active and gaining in body-weight. These experiments are in progress.

Fig. 4.—Brominated Film of the Oil.

A comparison of the extent of nutrition can be roughly drawn from Chart I in which the dotted line indicates the weights gained by the control rat on mixed diet, and the continuous line is that of rats on an exclusively nut diet during the short period they were under observation.

CHART I.

The curves are to all practical purposes parallel, showing that nutrition is almost the same in both cases.

Conclusion.—The fruit of *Anacardium occidentale*, the *Hijli Badam* of Bengal, grows lavishly in coastal sandy tracts and ridges, and the vast area of the coastal forests can be utilized for its cultivation. It is a really nutritious food and is unique as a supplementary staple food. It should not, however, be confounded with *jungli badam* which is neither so tasty nor commonly used for eating. It is rich in proteins, fat, iron,

phosphorus and other mineral salts which are so essential for the growth of the body.

Hijli Badam also yields a large percentage of edible oils which can be used as a substitute for ghee, and also as a substitute for almond oil on account of its soothing properties, and at the same time on account of its cheapness. Moreover the cardole has got various uses in external application as a medicine and for other domestic purposes.

A Mirror of Hospital Practice.

BILATERAL TORTICOLLIS.

By S. K. GUPTA, M.B.,

Halara, Jamalpur (Burdwan).

ABOUT a fortnight ago, I was called in to see a case at a distant village having the history of sudden turning back of the head, which occurred at about 12 noon on that day.

On arriving there at about 5-30 p.m. I saw a young healthy lady of 15 or 16 years, lying on her dorsal decubitus with her eyes open and head turned backwards.

She had been silent since the noon (as relatives said) but, on hearing that a doctor had come to treat her, she began to abuse me in bad language and exerted her whole strength to prevent me from examining her. However, I examined her thoroughly with the help of her relatives.

On physical examination no other abnormality but rigid contraction of the neck muscle was found. Pupils were equally and moderately dilated (due to semi-darkness in the room) reacting normally with light. Sense normal (closing her eyes if fingers are put there); the patient was conscious.

No history of hysterical fits or any other disease. Her relatives and other villagers on seeing her abusing me in this way, believed that she was caught by a *ghost* (*Bhut*) and requested me not to give her any medicine; and they wanted to drive the ghost (*Bhut* in Bengali) away by chanting sacred hymns (*mantras*).

But without listening to them I gave her an injection of morphine with atropine, a purgative containing calomel and a mixture containing hypnotics. I asked them not to disturb the patient from her sleep by chanting *mantras* and told them "if they do so the patient may die." Through fear, they did not venture to chant any *mantras*.

She had a very sound sleep during the night, followed by complete disappearance of all her symptoms in the morning. The relatives and villagers were greatly astonished to see that doctors could drive away ghosts with medicine more quickly than their *mantras*.

A CASE OF BLACKWATER FEVER.

By K. G. NAIR, L.M.P.,
Medical Officer, Balliguda,
and

S. RAJU, L.M.P.,
Malah Reserve Medical Officer, Balliguda.

AN Indian Christian girl, aged 15 years, a temporary resident of the Agency Tracts for a continued period of 6 years, very often subjected to malaria, had in the beginning of April an usual attack of fever which subsequently turned out to be blackwater fever. The history revealed that all the previous attacks were treated with some antipyretics or other, excepting the specific drug quinine which was resorted to very sparingly whenever the attack proved to be protracted and persistent. This last occasion was no exception to the rule. A purgative followed by aspirin and a diaphoretic mixture was used but the fever continued without response until the evening of 4th April, 1929. Then on the advice of the doctor 5 grains of quinine hydrochloride were given. Next day 10 grains were given with the result that the temperature came down considerably, enabling the patient to move about freely. At about 7 p.m. on 5th April, 1929, the girl while passing urine noticed the colour of it to be very dark. Fortunately a receptacle was used, and so that the doctor when summoned, was easily able to detect the signs of blackwater fever. Immediately the girl was confined to bed, and extract cassia beareana liq. was administered in hourly doses of 10 mins. Next day at about 10 a.m. pains in the loins started, which increased in gravity every minute, making the poor girl very restless and roll in the bed. Fomentations, pressure, and counter irritants did not mitigate the pain. The urine continued to be of the same colour and consistency, but the quantity became less. A hypodermic injection of morphia was given after some consideration. Much to the relief of the girl after a lapse of about half an hour the pain became bearable. Plenty of bland liquids and thin Horlick's malted milk combined with the mixture were given. Next day at about 9 a.m. nausea of a very bad type started which subsequently developed into vomiting. Every time green cheesy matter with some liquid was being brought out. Gastric sedatives which were attempted one after the other gave no relief. The patient became very exhausted, the pulse became rapid and feeble, and the temperature shot up to 103°F. Delirium started and the patient began sinking; this disheartened the relatives, not to speak of ourselves. Now the mixture containing cassia beareana was suspended and Sternberg's mixture in the doses suggested in *Manson's Tropical Diseases* was started. After a few doses of the mixture had been retained the nausea abated, allowing the girl to rest in short naps. This mixture was continued uninterruptedly, an ounce every hour, along with the diet and plenty of water. The next urine exhibited a definite change in the colour, consistency and volume. Gradually on the third day after the use of the second mixture the urine is cleared. On 10th April, 1929, i.e., the sixth day, an enema of soap and warm water was given, which further relieved the patient a good deal. By this time the temperature had come to normal. On 11th April, 1929, the mixture was suspended and the patient put on quinine. This was given in capsules in the form of hydrochloride in doses of 10 grains for over six weeks. Towards the end of June she was removed to a station on the plains. There was no trouble in the meanwhile excepting for an attack of gastritis.

Certain points of interest in this report of the case are, (1) the development of the attack after a long stay of 7 months in this part of the Agency which is not an endemic area, (2) a very reliable history of irregular dosing of quinine, (3) advantage of the Sternberg's mixture over cassia beareana liquidum and (4) advantage of starting quinine sufficiently early soon after the active period of the disease passes off.

Our thanks are due to Major F. R. R. Carreck, I.M.D., our District Medical Officer, for his kindness in reviewing and permitting us to publish this.

A SEVERE CASE OF OSTEOMALACIA.

By CAPTAIN R. P. GHOSH, M.B.,
Deputy Superintendent and Teacher of Surgery,
Darbhanga Medical School, Laheriasarai.

ON the morning of the 13th May, 1929, I was asked to see a Hindu woman, aged about 25 years, with the following history:—

She was six months' pregnant. Five days before she had had a fall followed by uterine hæmorrhage. A number of country *dais* were consulted and they decided to remove the fœtus as it was dead. They all tried to extract it, but to no effect. I examined the patient and found the following:—

A thin small woman looking desperately ill. Unable to extend the lower limb. Pulse, 140; respiration, 20; and temperature, 97°. Tongue, dirty and dry. Uterus up to the level of umbilicus. Through the vagina was coming out some pus-like fluid with an offensive smell. I found she was suffering from severe osteomalacia and, on attempting to make a vaginal examination, I found that the outlet hardly admitted my forefinger. Not being able to decide what to do under the circumstances, I consulted my chief Dr. S. M. Livesey, M.B., F.R.C.S., and he decided on hysterectomy, but, as the patient was in a bad condition, we decided to wait until there was some improvement. We gave her the usual restoratives, saline glucose *per rectum* and repeatedly douched out the vagina.

Next morning her pulse rate was 146 and temperature 97°. Dr. Livesey decided to perform a rapid hysterectomy, and so I gave her a breast saline. Under ether anaesthesia, the usual hysterectomy was performed, and both ovaries were removed. It took just 15 minutes from the time the skin of the abdominal wall was incised to the last stitching. Shortly after the operation the patient started showing signs of improvement and she made an almost uneventful recovery. A month later she left the hospital apparently a different woman altogether. It goes without saying that but for the rapid hysterectomy the patient could not have survived.

My best thanks are due to my chief, Dr. Livesey, for permission to publish this case.

A CASE OF PNEUMONIA TREATED BY "PNEUMOCOCCUS IMMUNOGEN (COMBINED)."

By MAHENDRA KUMAR BATTACHARYA,
Medical Officer, Bengal Police Hospital, Alipore.

THE patient, a male, aged 23 years, was first admitted into this hospital on 30th December, 1928, with complaints of dyspepsia and was treated accordingly up to 23rd January, 1929.

On 24th January, 1929, he suddenly complained of pain in the right side of the chest with rise of temperature up to 104°F., dyspnoea and restlessness. The chest was carefully examined, but nothing particular was found except harsh breath sounds on one side. The patient was placed on alkaline mixture and rest. The respirations were 24 per minute.

On 25th January, 1929, the temperature was between 104°F. and 103°F., and this was associated with a dry hacking cough and scanty expectoration. The previous signs and symptoms were pronounced. The respiration was 32 and pulse was 120 to 126 per minute. Fine crepitations were audible in the lower half of the right side of the chest, vocal fremitus was increased and dullness was also detected, and the patient was slightly delirious: A complete blood count was done and the result was as follows:—

Hæmoglobin 66 per cent.
Erythrocytes 3,200,000 per c.mm.
Leucocytes 25,000 per c.mm.
Polymorphonuclears 90 per cent.
Lymphocytes 7 per cent.
Large mononuclears 3 per cent.
Eosinophiles Nil.

The alkaline mixture was continued 4 times a day. Calcium lactate, grs. x, twice daily for 48 hours was given and Antiphlogistine applied to the chest. Pneumococcus immunogen was withheld until the diagnosis of lobar pneumonia could be definitely established.

On 26th January, 1929, no improvement of the patient was found, but signs of toxæmia were pronounced; the patient was more delirious and respiration much increased and difficult, i.e., 42 per minute. The pulse was full, soft, and very frequent, i.e., 125 to 130 per minute, and the patient was more restless. The dullness had increased. The temperature was running between 103 to 104.2°F.

On 27th January, 1929, an intramuscular injection of pneumococcus immunogen (combined) in $\frac{1}{2}$ c.c. dose was given at 4 p.m., in addition to the medicine prescribed previously. Besides, he was given rum in drachm doses, 4 times a day, and digifortis 3 times a day in 10 minim doses. The temperature was running between 103.4 to 104.4°F.; the respiration was 44 to 46 and the pulse rate was 130 to 134 per minute.

On 28th January, 1929, the signs and symptoms were less pronounced, the temperature was running between 102°F. and 103°F. The patient was less delirious and less restless. Respiration was 40 to 43 and pulse 124 to 131 per minute. He complained of less pain. The same treatment was continued except the pneumococcus immunogen.

On 29th January, 1929, the temperature was running between 102°F. and 102.6°F. and the general condition of the patient was much better. The same medicine was continued and a second dose of 0.75 c.c. of pneumococcus immunogen (combined) was injected intramuscularly. Respiration was 36 to 40 and pulse was 119 to 124 per minute.

On 30th January, 1929, the temperature was running between 100.6°F. and 101°F., the respiration was less difficult—i.e., 33 to 35 per minute—and the condition of the pulse was much improved, i.e., 115 to 119 per minute. There was no delirium. The chest was examined and moist ronchi were audible. There was slight rusty expectoration. In order to observe the case I had to give him at 8 a.m. the 3rd dose of 1 c.c. of pneumococcus immunogen. The temperature next morning came down

to 97.4°F. He was then placed on stimulant cough mixture and stimulant mixture, digifortis 3 times a day for 48 hours—then a stimulant cough mixture and subsequently an iron tonic were continued for some time. He had no rise of temperature till the 7th February, 1929. Respiration was 26 to 28, pulse was 105 to 108.

But on the following day (i.e., on the 8th February, 1929), he had a slight rise of temperature 99.2°F. Probably this rise of temperature was due to some more diet having been given to the patient. Since then he had no rise of temperature and his general condition gradually improved and he made an uninterrupted recovery subsequently.

The case is an example of the effect of immunogen on the course of the disease.

The improvement in pulse rate and general condition was very marked from the beginning of the treatment.

I thank Lieut.-Col. A. Denham White, I.M.S., Civil Surgeon, 24-Perganas, for kindly permitting me to publish the above report.

APHONIA FOLLOW QUININE ADMINISTRATION.

By N. S. KRISHNA IYER, B.A., L.M. & S.,

Calicut.

On the afternoon of 12th October, 1929, I attended on a case of fever of 2 days' duration. The patient was a young girl, aged about 16 years; when I saw her, her temperature was 103.8, pulse 126 per minute, respirations slightly accelerated, tongue coated, and bowels a little loose. The history given by the patient seemed to suggest a diagnosis of malarial fever.

I thought of trying a few doses of quinine mixture on her and accordingly 4-grain doses of quinine sulphate were prescribed. The first dose of the mixture was administered at 2 p.m. At about 6 p.m., the patient began to lose her power of speech; the condition gradually got worse and worse until by 10 p.m., she could articulate no words at all. The patient's relatives naturally grew anxious about her and I had to go and see her again.

The patient's condition was much the same as it was in the afternoon except that aphonia was present. She was entirely conscious, could open her mouth, protrude her tongue out well and could understand everything that I said to her, but she herself could make no sort of a reply. After great pressure on my part she just uttered correctly the number of the fingers which I was exhibiting before her.

I told the relatives not to be anxious about her condition which would soon pass off, and not to give her any mixture for the night.

The condition improved during the night, and she was all right next morning, when, without consulting me, another dose of the mixture was given. This time also, after just the same interval as before, 4 hours, the aphonia supervened and lasted till the evening of that day.

The mixture was necessarily withdrawn, the patient was put on diaphoretics and, made an uneventful recovery.

Though disturbances of vision and hearing are occasionally met with, yet aphonia is seldom been reported and the rarity of the condition justifies the above description of my recently encountered case.

A CASE OF FRACTURE-DISLOCATION OF THE CARPAL SCAPHOID (NAVICULAR).

By MILITARY ASSISTANT SURGEON C. D. TORPY,
M.M.F. (B.), I.M.D.,

*In-charge, Radiological Department, British Military
Hospital, Trimulgherry.*

TROOPER A. was thrown off his horse at the riding school; he sustained what was thought to be a simple sprain of the right wrist. He was treated by palliative measures for this condition for over a month without any

and with a fuller range of movements of the wrist, the disuse atrophic appearances soon disappeared.

The important points in this case are:—

1. Without a radiological examination, a correct diagnosis could not have been arrived at, which emphasises the importance of having all severe "sprains" radiographed.
2. The tripartite nature of the fracture.
3. The amount of "disuse atrophy" that soon followed the lesion.

improvement. He was then sent for radiological findings as a " ? T.B. wrist."

The skiagram revealed an unusual tripartite fracture-dislocation of the carpal scaphoid (navicular). There was a total loss of architectural appearance of the metacarpals, and of the lower ends of the radius and ulna, a condition characteristically typical of a "disuse atrophy."

Fractures of the scaphoid are usually of the "snapped waist" type with little or no displacement, but in this case the tripartite nature of the fracture with the displacement of the fragments offered some difficulty in arriving at a diagnosis.

With the aid of stereoscopic pictures, two of the three fragments were removed by surgical operation later;

SPECIAL ARTICLES.

ARS OBSTETRICA.

By V. B. GREEN ARMYTAGE, M.D., F.R.C.P. (Lond.),
LIEUTENANT-COLONEL, I.M.S.,

*Professor of Obstetrics, Calcutta Medical College, and
Surgeon to the Eden Hospital.*

Renal Disorders and the Toxæmia of Pregnancy.

DURING recent years many papers have appeared on this subject, notably those by Caldwell, Lyle, Harris, F. J. Brown, James

Young and Gibbard. As a result of the study of many hundreds of cases we now can assume that there are four definite clinical types:—

1. The nephritic type. Patients with chronic nephritis preceding pregnancy. These patients continue with signs of renal deficiency after pregnancy.

2. Patients presumably healthy before pregnancy, who develop albuminuria during pregnancy, but in whom all signs and symptoms of renal disease disappear after delivery, and do not recur with subsequent pregnancy. These form 40 per cent.

3. Patients presumably healthy before pregnancy, who develop albuminuria during pregnancy and in whom all signs and symptoms of renal disease disappear after delivery, but recur regularly with subsequent pregnancies. These form 50 per cent.

4. Patients presumably healthy before pregnancy who develop albuminuria during pregnancy, but in whom all signs and symptoms of renal disease persist permanently after delivery. These form 10 per cent.

It may be stated therefore that recurrent albuminuria may be looked upon as due partly to a subliminal pregnancy toxæmia, and partly to a pre-existing occult nephritis, caused by the first toxæmic pregnancy. *Hence we may state that pregnancy itself is the most delicate test of renal function that we possess.*

F. J. Brown has conclusively proved by experiments that antepartum hæmorrhage is not due to organisms, but is due to either chronic nephritis interfering with the normal metabolic function of the kidney, or to failure of the kidney to excrete poisons which eventually lead to hæmorrhage when they have accumulated in the circulation in sufficient concentration.

Treatment.

The above observation of clinicians have led to the following didactic principles of treatment:—

1. Seeing that toxæmia is most lethal to the *fœtus in utero*, we have no justification for gambling with the life or health of the mother in the interests of a child whose survival is problematical. Holland, in a series of 351 *fœtal* deaths, demonstrated that 77, that is 26 per cent., were caused by albuminuria, eclampsia, or accidental hæmorrhage, and that the mother's future health was jeopardized in 50 per cent.

If the manifestations are slight and the patient is under adequate supervision, one may safely temporize whilst viability of the *fœtus* is possible, but if there is marked œdema, a blood-pressure 30 or 40 mm. higher than it should be, a heavy deposit of albumen in the urine, and more especially if there are headaches and visual symptoms, to delay is dangerous.

2. In all toxæmic patients who are seen before the seventh month, delay is rarely justified in the interests of mother or infant, and especially is this so if the woman has suffered renal damage in a previous pregnancy.

3. For ordinary routine purposes where urgency is not immediate, the best means for the induction of premature labour is the bougie or stomach tube method, followed up if need be by the castor-oil-quinine-pituitary technique.

4. For cases of grave urgency the above methods are too slow and uncertain. The best plan is to perform Cæsarean section under spinal anæsthesia, with ligation of the tubes if there has been toxæmia in a previous pregnancy, for no woman should be exposed to further risk of conception if she has had two or more toxic pregnancies.

5. As regards the dietetic treatment of the albuminuric pregnancy patient in the acute stages, the best results have followed the Van Noorden plan of giving nothing but fruit juice, sugar and water with just sufficient alkalis to render the urine alkaline until there are no red blood cells present.

For the treatment of the œdema when the urine is free of blood, the following diet scheme of Langdon Brown is recommended.

1. Low Nitrogen Diet.

Breakfast.—Milk 4 oz., porridge 8 oz., bread 2 oz., butter $\frac{1}{2}$ oz. Fluids: Coffee 10 oz., milk 2½ oz.

Lunch.—Bread 3 oz., butter $\frac{1}{2}$ oz., lettuce or tomato 1½ oz. Fluids: Milk 5 oz., barley water 10 oz.

Dinner.—Potato 4 oz., greens 5 oz., butter $\frac{1}{2}$ oz., stewed fruit 4 oz., boiled rice 4 oz. Fluids: Lemonade, imperial drink, or barley water 12 oz.

Tea.—Bread 3 oz., butter $\frac{1}{2}$ oz., lettuce or tomato 1½ oz. Fluids: Weak tea 10 oz., milk 2½ oz.

Supper.—Potato 4 oz., butter $\frac{1}{2}$ oz., greens 5 oz., stewed fruit 4 oz. Fluids: Lemonade or barley water 12 oz.

This diet contains: Protein 49 grams; carbohydrate 358 grams; fat 35 grams. Caloric value, 1,992.

2. Moderate Nitrogen Diet.

Breakfast.—Egg 1 oz., bread 2 oz., butter $\frac{1}{2}$ oz. Fluids as in No. 1 diet.

Lunch.—Bread 4 oz., butter $\frac{1}{2}$ oz., tomato or lettuce 1 oz. Fluids as in No. 1 diet.

Dinner.—Mutton or fish 3 oz., bread (alternate days) 2 oz., butter $\frac{1}{2}$ oz., stewed fruit 4 oz. Fluids as in No. 1 diet.

Tea.—Bread 4 oz., butter $\frac{1}{2}$ oz., tomato or lettuce 1 oz. Fluids as in No. 1 diet.

Supper.—Greens 2 oz., potato 3 oz., bread 4 oz., butter $\frac{1}{2}$ oz., stewed fruit 4 oz. Fluid: Milk 5 oz.

This diet contains (on average): Protein 64 grams; carbohydrate 407 grams; fat 91 grams. Caloric value, 2,772.

These diets proved suitable in the experience of other observers also. Alcohol is certainly undesirable in azotæmic nephritis.

The efficiency of the kidney is periodically tested by the urea concentration test. Dr. Brown suggests, if need be, 1 to 2 drs. of ammonium chloride should be given on each of two days, and then on the third day a half to 1 c.c. of novasurol are injected intramuscularly. This treatment for the œdema can be repeated after a few days.

The Management of Pregnancy Complicated by Heart Disease.

Whether or not to allow a woman with heart disease to go through pregnancy, that is the question, for we have to decide whether or not the heart will be able to supply blood for the physical demands of the later

months of pregnancy, and especially for the strenuous effort of the hours of labour.

In the past the diagnosis of the anatomical lesion has been used as a basis for prognosis, but this is not an entirely reliable basis, for Sir James Mackenzie pointed the way to a better understanding of the problem by focusing attention upon the signs and symptoms of failure of the heart to maintain a normal circulation; hence we may lay down the maxim that *the prognosis of pregnancy depends upon the functional cardiac diagnosis, that is the patient's ability to perform physical exertion.*

The New York Heart Association has done a good service to all obstetricians by dividing all organic cardiac pregnancy cases into four classes according to their cardiac functional capacity:—

Class 1.—Those who are able to perform ordinary and usual physical activity without unusual fatigue, palpitation or dyspnoea.

Class 2.—Those who are able to perform their usual normal activity but who have discomfort in so doing, e.g., shortness of breath after climbing stairs or housework.

Class 3.—Those who are unable to perform the more difficult features of ordinary physical activity, e.g., climbing two flights of stairs, or walking half a mile without stopping on account of fatigue or palpitation.

Class 4.—Those who are unable to perform the simplest physical activity, e.g., inability to walk 100 yards, or climb a stair, or do any housework without dyspnoea or palpitation.

In hospital or consulting room, a test exercise such as asking the patient to swing a 5 to 10 lb. dumb-bell from between the legs to straight overhead 20 to 25 times is of considerable help, for the physician can note the pulse rate and general reaction and especially the occurrence of dyspnoea as the exercises proceed, and can then classify her accordingly.

Pardee reports 112 patients with heart disease tested by these means in the antepartum clinic of the New York Lying-In Hospital: 75 were diagnosed as Class 1; 20 as Class 2; 11 as Class 3; and 6 as Class 4.

Of the 75 patients in Class 1; 60 entered hospital for delivery and there was no cardiac embarrassment during or after labour.

Of 20 patients diagnosed as Class 2; 12 entered hospital, 5 went through perfectly uneventful labours, 6, however, with varying fortunes as to the duration of labour had for a short period increase of pulse and respiration rates with slight dyspnoea, but all recovered. One died of pulmonary embolism.

Of 11 patients in Class 3; 9 entered hospital, 3 were delivered uneventfully, 2 had considerable cardiac embarrassment, 2 had Cæsarean section and recovered, but 2 others died after operation.

The great difficulty in predicting the effect of labour is the inability to foresee the duration and severity of the strain in each case. With a short first stage and a short second stage, perhaps assisted by low forceps, there may be little strain

imposed upon the heart, but a long second stage is disastrous to a weak heart muscle.

If a woman is in Class 4 when seen, and her heart fails to respond to expert treatment after two or three weeks, the pregnancy should be terminated by that method which combines the utmost speed with a minimum of cardiac strain, either under chloroform, ether, or local anaesthesia. Spinal anaesthesia should be never used in these cases.

Puerperal Pyæmia.

An interesting discussion has recently occurred on the question as to whether surgical intervention is justifiable in puerperal pyæmia. Polak points out that after expulsion of the placenta there is normally obliteration of the uterine vessels, but if such thrombi become inoculated with pathogenic bacteria the thrombus becomes liquefied and the intima eroded with the escape of pus cells or infected emboli into the circulation.

Should the cellular defence of the individual be small, and the virulence of the infection great, the organisms are practically in pure culture, and inevitably the patient will die whatever treatment is adopted. On the other hand, if the cellular reaction of the blood is sufficient, or the organisms are of low virulence Nature will provide additional defensive thrombo-phlebitis, and it is found in practice that these patients recover in 60 per cent. of cases without operation. Our experience in the Eden Hospital of these cases is a very large one and corroborates this view, but the great difficulty which befalls every clinician is to make an accurate diagnosis of the pathological problem early enough to warrant surgical interference.

The clinical picture to my mind is not sufficiently distinct in the majority of cases to warrant a hazardous laparotomy with a mortality of 50 per cent. even when done at the earliest opportunity, for conservative treatment on the lines of auto-vaccine therapy, small repeated direct blood transfusions, and quinine injections give at least a 60 per cent. recovery, provided all pelvic manipulation is avoided.

A diagnosis of puerperal pyæmia may be assumed in the presence of the following:—arrested involution, profuse red lochia, after pains, and the passage of clots. Repeated rigors indicate bacterial escape beyond the confines of the thrombus. The rise of temperature to 104 or 106 which follows such escape, and is succeeded by a sudden remission to normal with profuse sweating, shows that the veins are temporarily blocked by new clot formation. Such a clot in a few hours again becomes liquefied and the clinical syndrome is repeated. The pulse rises with the temperature but does not show a proportionate fall. The hæmoglobin percentage rapidly diminishes and there is progressive anaemia due to destruction of the red blood cells. As a rule there is leucopenia and a low blood platelet count.

The Bacteriology of the Puerperium.

The normal uterus is bacteriologically sterile immediately after delivery, but gradually becomes infected from then onwards, so that 25 per cent. of all cervical cultures are positive on the first day, 50 per cent. on the second day, and 100 per cent. on the third day of the puerperium. Moreover, it has been proved that infection of the fundus uteri concomitantly occurs, reaching its maximum on the fifth day and then diminishing.

Armstrong and Burt White have shown (1) that *S. pyogenes* is found frequently in the cervix without any symptoms of disease, but in such cases it is always in association with other organisms.

(2) If *S. pyogenes* is found in cases of puerperal sepsis, the severity of the illness is in proportion to the number of streptococci present, and that the body of the uterus is rapidly invaded from contiguous surfaces early in the puerperium.

(3) The severity of puerperal sepsis is proportionate to the trauma of childbirth, whether natural or artificial.

(4) Mellanby has found by experiment that much of the decreased resistance of an individual to bacterial invasion is due to deficiency of vitamine A in the mother's body, for the foetus *in utero* throughout pregnancy unakes great demands upon the maternal store and supply of vitamine A, and most particularly of that store in her liver. On this hypothesis Professor Mellanby, in co-operation with the authorities of the isolation block of the women's hospital of Sheffield, treated a number of cases with two preparations (X and Y) of vitamine A which were respectively 10 and 150 times more rich in vitamine A than cod-liver oil.

Substance X was given in 2 dr. doses twice a day, substance Y was given in 2 drop doses 12 times a day in orange juice.

Substance X is radiostoleum supplied by the B. D. H. Substance Y was supplied by Lever Bros.

Five cases of hæmolytic streptococcal septicaemia were treated, they all recovered.

Mellanby is of opinion that the effect of vitamine A is rather to increase gradually the general resistance, than to act suddenly as might be expected in the case of a substance having a specific bacteriocidal or anti-toxic action. He found that blood cultures from these patients became sterile within a fortnight of the administration of vitamine A.

These five cases are of course too few in number to permit the deduction that this form of treatment is specific for septicaemia, but it does warrant the belief that vitamine A plays an important part and has the property of raising the resistance of the body to bacterial infection.

This research work will I am sure be appreciated in India, for the anti-infective action of vitamine A will probably be shown to be equally potent in all cases of bacterial invasion: we should particularly welcome this work from the prophylactic point of view in obstetrics for it proves the

importance of such foods as fresh eggs, green vegetables, milk, butter and cheese, all of which contain vitamine A for the expectant mother, and should there be suspicion of difficult labour, then how easy is it to order radiostoleum for one month before confinement.

Inversion of the Uterus.

The question of immediate treatment of the inverted uterus has always been a moot one, some authorities advising restitution, others advocating that the organ should be left in its undignified position, although all are agreed that nothing should be done whilst the patient is suffering from shock.

My reason for mentioning this subject is that it is not generally recognized that spontaneous reduction of an inversion frequently occurs, and that if there has been much trauma, oftentimes the patient dies of sepsis if the uterus is manually replaced.

Boxall, Comyns Berkeley, Miller, McCullagh, and Phillips have all recorded cases of spontaneous restitution, therefore it may be stated that if obvious signs of sepsis are present, the inverted uterus should be left untouched save for the removal of placental remains, and saline lavage given daily until all discharge ceases and the uterus becomes firm. Then if manual or instrumental replacement fails operation is permissible.

In India most of the cases of inversion of the uterus are horribly septic when first seen, days after delivery, therefore practitioners should bear in mind that sepsis inside a soft involuting uterus, lacerated and contused by reduction, predisposes to septicaemia, parametritis or phlegmasia alba dolens with death or a protracted convalescence.

Postnatal Maternal Care.

(1) It has been said that 60 per cent. of gynæcology is made up of lesions secondary to childbirth. It is therefore an obvious corollary that the degree of skill and care with which the process of delivery is conducted is an important factor for a woman's subsequent well-being.

Ante-natal care has come to stay, but after the crisis of labour there is apt to occur an anti-climax in which the care and watchfulness of the physician tends to relax, with the result that the patient passes out of his vision without a single postnatal examination. This is wrong, for there are a host of disabilities which may beset the young mother. It is my experience that the body, muscles and tissues take at least 10 weeks to resume their normal, after the lying in period and it is for that reason that massage, postural and abdominal exercises are so important, for visceroptosis is extraordinarily common in India. Indeed many women are the better for the wearing of a Curtis or similar belt for many months after labour. In addition in the tropics the gaping, relaxed vaginal outlet is a constant source of exasperation to both husband and wife; this condition is due to stretching and non-involution of the sphincteric muscle fibres together with the

levator ani. It can be rectified by the Stacey Wilson exercises which I have detailed in a previous publication.

(2) In at least 30 per cent. cases retroversion of the uterus occurs, which is responsible for back ache and blood discharges. Routine examination of every patient about the sixth week after labour would obviate such symptoms, for the temporary application of a pessary will cure the majority of such patients.

(3) Laceration of the cervix followed by infection and erosion is present in at least 20 per cent. of cases after the first baby. Such laceration is a frequent cause of troublesome symptoms and occasionally of one child sterility.

Immediate treatment, two or three weeks after labour with a 10 per cent. solution of silver nitrate, or the use of the electric cautery which can be done without an anæsthetic will cure the majority of these cases; others, however, will need operative measures.

(4) Sub-involution due to sub-acute infection or subsequent to difficult labour is responsible for much ill health, apart from the fact that the uterus usually drops downwards and backwards giving rise to back ache, discharge and possibly dysuria. Replacement and support of the uterus are beneficial but occasionally Hobbs' glycerine treatment will be found most beneficial.

(5) It is necessary to mention sacro-iliac pain for it is by no means uncommon in the tropics for women to complain of pain in sitting or rising after their first labour, due to stretching of the joint ligament, and often you will find that so-called coccygodynia is referred pain from the sacro-iliac joints. Such cases can be treated by massage or the use of special belts which strap across the hips.

Occasionally an under-lying prolapse or constipation with visceroptosis are responsible for symptoms referred to the lumbosacral regions.

(6) Infection of the cellular tissue of the pelvis often exists, the result of a prolonged or difficult labour. This condition is as a rule missed by the practitioner who is not an expert in vaginal examinations, for the cellular infiltration usually involves the uterosacral ligaments or possibly the parametrium on one side, without involvement of the tubes and ovaries.

Such a case can be diagnosed accurately by putting the tissues on the stretch when making a vaginal examination: if for example the cervix be pushed by the finger towards the right you elicit a left iliac pain, or by pushing it forwards you produce a sacral pain, you can diagnose that the old inflammation is in the parametrium or uterosacral ligaments as the case may be.

Frequently in such a case you will find the cervix is permanently dislocated by the cicatricial contraction following cellulitis.

(7) One child sterility is a frequent cause of anxiety. Apart from gross lesions following childbirth, it frequently is caused by a low grade form

of sepsis which has travelled upwards from the cervix eventually involving the tubes.

Short of an abdominal operation, only a Reuben or Lipiodol test can discover this, for it is the rule rather than the exception in the class of case that I am discussing to find nothing whatever palpable vaginally.

Lastly, quite apart from mental disorders, occasionally we meet with cases of endocrinal dysfunction after pregnancy, where the patient has complete amenorrhœa, puts on weight, becomes apathetic and her skin is dry. These are cases of pituitary and thyroid hypofunction, and in them you will expect and find one child sterility.

It has been suggested that the cause of this dysfunction is a poison absorbed from some local focus which injures the endocrine system. The teeth, the tonsils or the cervix are probably the criminals.

Cæsarean Section.

Ivens has recently recorded a consecutive series of 295 Cæsarean section with a mortality of 1.3 per cent. This remarkable result included clean, potentially septic, and frankly septic cases. She drains the abdominal cavity for 48 hours in septic cases, and gives them at the time of operation 30 c.c. of anti-streptococcic serum. This record of success still further encourages us to preach against the indefensible attitude of those in India who prefer to do a craniotomy on a living child rather than infinitesimally risk the life of the mother by Cæsarean section, for the maternal mortality of craniotomy in India is greater than that of Cæsarean section, whether the case be septic or not.

White Asphyxia.

In 1926 I cited the work of Dame Louise MacIlory on this subject; since then we in the Eden Hospital and many other workers have corroborated her findings and insisted that the proper treatment of these infants is that of shock, for in the majority of cases they have just suffered severe mechanical cerebral stress, and anything in the shape of strenuous artificial respiration is only piling Pelion upon Ossa, or making bad conditions worse.

Time and again we have noted in our hospital, when women have been brought in late, for delivery by forceps or Cæsarean section, that if the toneless asphyxia pallida baby has had the mucus extracted from its throat, and has had 5 minims of adrenalin injected into the heart and is kept in a hot bath for an hour or more, that it begins to breathe as the shock of delivery passes off. While in the bath it is our routine to pass a middle finger into the rectum, or dilate with forceps the foreskin. Sometimes half a c.c. of pituitrin or one-sixtieth of a grain of strychnine are given into a muscle. On these lines practitioners will save a great number of these infants, which in previous days would have been treated by such abominable and disappointing methods as those of Shulze's artificial respiration which frequently causes intraspinal hæmorrhage.

In those cases that do not survive, or such as have had vigorous Sylvester artificial respiration, it is by no means uncommon to find that the cause of death is either subdural hæmorrhage from rupture of the tentorium cerebelli, or damage to the suprarenal capsules.

Dame Louise MacIlroy has recently demonstrated that good results may follow in many cases from the administration of carbon dioxide gas; this is extremely interesting for the principle is the very reverse of artificial respiration.

Placenta Prævia.

The pendulum gradually is swinging away from the old time treatments. When I was a student version was looked upon as the best method, but to-day team work and follow-up clinics, together with systematic consideration of the various methods of treatment, point to the fact that version, and for that matter, plugging, are means which are hardly justifiable except in an emergency by the general practitioner far from hospital aid.

Immediate hospitalization is the first essential, directly diagnosis is clear. In the majority of cases of lateral and marginal placenta, simple rupture of the membranes with the application of Willett's vulsellum to the foetal scalp, gives the smallest foetal and maternal mortality, for the great principle of treatment is to compress the bleeding point and what better compressor do we possess than a hard foetal head. It is our custom to attach a one pound weight to the handle of the Willett forceps; the bleeding stops, the cervix dilates and the risk of tearing the cervix is far less than in the case of version, which every one knows is by no means an easy operation for the general practitioner. Willett's vulsellum is cheap and very easily applied through a cervix which admits two or even one finger. It is my opinion that this method should be more generally known and used in this country.

Cases do occur, however, which indicate a more general use of Cæsarean section. I refer to patients with central placenta prævia who are primiparæ or in whom the os is hard and not dilated more than one finger, or in whom the pelvis is contracted or the foetus near full term. The mortality in these cases treated by other means is appalling, the mother dying in over 40 per cent. of hæmorrhage or sepsis, whereas the infant is born dead in over 80 per cent.

When discussing this problem last year in Berlin, Vienna, Munich and Zurich, I was not surprised to find that the consensus of opinion was all in favour of Cæsarean section, several professors informing me that their maternal mortality had been reduced to less than 10 per cent. and their infantile mortality to under 20 per cent. since they adopted Cæsarean section as a routine method.

This being so, it behoves us to relax our somewhat rigid and conservative attitude as regards treatment for those cases where the foetus is alive, and the general condition of the patient indicates

that better results as regards both mother and child will be obtained by Cæsarean section.

Finally, in this connection may I appeal for two things which are long in becoming popular in India, namely, immediate hospitalization and the wonderfully beneficial effects of direct blood transfusion, for the excellent results obtained in Great Britain, America and the Continent depend to a very large extent on these two factors.

THE EVOLUTION OF MEDICAL PROTOZOOLOGY.

[Being the presidential address to the Medical and Veterinary Research Section of the Indian Science Congress held at Allahabad in January 1930.]

By R. KNOWLES,

LIEUTENANT-COLONEL, I.M.S.,

Professor of Protozoology, Calcutta School of Tropical Medicine.

(Illustrated by lantern slides.)

LADIES AND GENTLEMEN,

My first duty is to thank you and the Council of the Congress for the very great honour which you have done me by asking me to preside at the present meeting of the Section; an honour which I most deeply appreciate, not so much on personal grounds, as on behalf of the Calcutta School of Tropical Medicine and Hygiene. The Indian Science Congress is the one opportunity which scientific workers in India have annually of getting together and comparing notes; as such it is essentially the most important stimulus to scientific research work in this country.

I have been much exercised in mind as to what subject to choose for this address. For the past nine years my work has centred entirely on problems in medical protozoology, and what has impressed me more and more in the study of this subject is the large and important part which workers in India have played in the development of this new science. I have therefore chosen the evolution of medical protozoology—or, better, of medical protistology—as the subject of my address; for there are many lessons from the past for the worker of the present and the future.

The history of protozoology is almost the history of the evolution of the microscope, since the vast majority of protozoa are so minute that they cannot be studied without a microscope. The father and founder of the science, Antony van Leeuwenhoek (1632–1723), was one of the most marvellous men who ever lived. "This old Hollander," writes Dobell (1922a) "was, in truth, one of the most original men who ever lived. It is impossible to compare him with anybody else, for he belongs to a genus of which he is the type and only species. Your typical scientific genius gets a good education; Leeuwenhoek got practically none. He goes to a university and studies under distinguished professors; not so Leeuwenhoek. He imbibes the traditional knowledge of centuries and then begins to re-arrange and develop it for himself; but all that Leeuwenhoek knows he has learnt himself from Nature, and when he sets to work he relies entirely on upon his own native genius. He cannot even read what others have written on the subjects that interest him. He can only talk to Nature, ask her questions in 17th century Dutch, and puzzle out her answers by himself."

Leeuwenhoek was born in 1632 at Delft and came of good Dutch stock. He was probably fairly well-to-do, and married at the age of 22. During most of his long life he held the post of Chamberlain to the Sheriffs of Delft, an office which was probably a sinecure, and devoted his entire time to microscopic studies. He began at the very beginning by learning how to grind and mount lenses. With infinite patience and infinite perseverance he devised every piece of apparatus which he used, repeating his experiments again and again in order

to convince himself of their accuracy. He ground all the lenses which he used, and even extracted the silver from its ore in which to mount them. In all he is known to have made and mounted some 400 lenses, some of them having a magnification of 300 or more diameters. With these lenses, Leeuwenhoek commenced to examine every fluid that he could think of, commencing with his own bodily secretions and excretions. For forty years he laboured in complete obscurity, working carefully, incessantly, patiently, and laboriously.

The Royal Society of London had its first origins about 1645, and was officially founded in 1660. Its Secretary wrote to different scientists all over Europe, asking for scientific contributions. One of these letters found its way into the hands of Dr. Reiner de Graaf (whose name is associated with the Graafian follicle), and who was a friend of van Leeuwenhoek. He communicated its contents to Leeuwenhoek. Thereafter Leeuwenhoek periodically wrote letters to the Royal Society describing his observations. It is in this series of some 200 letters extending over the last fifty years of his life, that Leeuwenhoek described his discoveries. During a large part of that period Great Britain was at war with Holland, but still the letters were smuggled through. He was made a Fellow of the Society in 1680, when 47 years of age, and this appears to have stimulated him to further efforts. This wonderful series of letters, written in 17th century Dutch, in a clear scholarly hand, fully illustrated with pen and pencil sketches and drawings, is still extant, being preserved in four large folios in the library of the Royal Society. The letters are to-day as fresh as if they had been written yesterday. In one of the folios attached to a page of the manuscript is a tiny envelope made of tissue paper containing some of his free-hand botanical sections of a plant, sections now 250 years old, but perfectly fresh and still suitable for mounting to-day.

The immensity of the Leeuwenhoek's observations is almost incredible. He studied the capillary circulation, and the blood corpuscles of different species of animals; also the histology of all manner of plants and animals. He was the first person to see spermatozoa, to see bacteria, to see spirochaetes, to see protozoa. He investigated the life history of the louse, the flea, and the ant, and discovered parthenogenesis in the Aphids. He discovered Hydra and its reproduction by budding; he discovered the viviparous reproduction of the vinegar eel; he discovered the Rotifers and their power of surviving desiccation. Animal and vegetable embryology, crystallography, the microscopic study of chemical compounds, were all subjects of his investigations. The letters are not of the character of scientific memoirs, but are familiar conversations, conveying a vivid and delightful impression of the charm and personality of the writer; long, rambling, couched in the colloquial style of his age and country. Yet they created both bacteriology and protozoology, where before there had been neither science. Everywhere he draws a clear differentiation between what he has seen, and what he infers; "I have observed" he writes of the former; "I figure to myself" he writes with regard to the latter.

It appears to have been in 1674, according to Dobell, that Leeuwenhoek first saw protozoa. The next year he was observing and studying protozoa in rain water, canal water, infusions of pepper, ginger, and nutmegs, and elsewhere. Naturally the first protozoa which he discovered were free living ciliate or flagellate protozoa, and his descriptions of *Vorticella*, *Stylonychia*, *Bodo*, are stated by Dobell to be so accurate that anyone familiar with these organisms would recognize them from his descriptions. In 1674 he was the first person to see a parasitic protozoon—oöcysts of *Eimeria stiedae*, the coccidium of the rabbit; though he did not know what they were. In 1681 he discovered *Giardia intestinalis* in his own stools, and gave a detailed account of this parasite. In 1683 he discovered *Opalina* of the frog, and also probably *Nyctotherus* of the frog. In 1680 he discovered anaerobic bacteria in pepper infusion, and in the same year yeasts in beer. In 1681 he discovered the bacteria of the human mouth and intestine—

including the spirochaetes. He saw and correctly interpreted the cilia and cirri of ciliate protozoa, and the flagella of flagellate protozoa; and even observed and correctly interpreted conjugation amongst the Ciliata.

Leeuwenhoek did not realize the full importance of his discoveries—nor did anyone else in his day. He was content to observe constantly, discover, and describe; contradiction, censure and even ridicule did not affect him; "It doesn't bother me," he writes, "I know I'm in the right."

And so we may leave this wonderful old Hollander, who for fifty years instructed the scientific world of Europe. He died in 1723 when nearly 91 years of age, still working and observing to the end of a long and ever memorable life.

A little later than van Leeuwenhoek was Louis Joblot (1645—1723), Professor of Mathematics, Geometry, and Perspective at the Royal Academy of Painting and Sculpture in Paris. During his tenure of office his chief attention was turned to the study of optics and microscopy. With the assistance of a scientific instrument maker in Paris he constructed microscopes of various patterns and then used them in the investigation of microscopic animals. His book on microscopes was published in 1718, and the second half of it, illustrated with 12 plates, is devoted to his study "of an innumerable multitude of insects and other animals of divers species." Many of Joblot's "insects" or "fishes" were protozoa, and Dobell (1922a) considers that this second portion of the volume "is, in fact, the first separate treatise ever written on the 'Infusoria.' It contains the first account, and the earliest published figures of many different protozoa—some of them easily recognizable, but a number not identifiable with any certainty." Joblot used no names for the ciliates which he was studying, but used such terms as 'bagpipes,' 'funnels,' 'kidneys,' 'gluttons,' 'pirouette dancers'—'the slipper' for *Paramecium*, and 'the swan' for *Amphileptus*. His work is chiefly remarkable for the experiments which he conducted to disprove the possibility of spontaneous generation, a matter in which he was precursor of both Spallanzani and Pasteur.

From 1723 to 1786 the field of protozoology lay almost fallow. Many zoologists regarded with doubt and misgiving everything seen with the microscope, though in those days continuous progress was being made in the perfection of that instrument. The great Linnaeus (1707—1778) appears to have always been suspicious of the Protozoa—*Chaos infusorium* is the name which he adopts for a whole series of questionable protozoal organisms. The embryonic science of protozoology was regarded rather as a suitable afternoon amusement for children than as a serious subject. Attention was naturally chiefly focused on the so-called 'Infusoria,' since these large free-living ciliate protozoa are so readily obtained in vegetable infusions, and are relatively large objects for study. Then in 1786 came Müller's book upon the Infusoria, published posthumously. "It is a remarkable work" writes Dobell; "full of shrewd observations, and showing astonishing insight, but containing of course many mistakes which were inevitable at that period. Many of the protozoa described and sketched by Müller—mostly from examinations made, as were those of Leeuwenhoek, with the aid only of a simple lens—are easily recognizable now by a protozoologist."

Up till about 1840, protozoology remained the perquisite of the micrographers, rather than a special branch of zoology. This period saw in 1838 the publication of Ehrenberg's great classic on the 'Infusoria.' It was a monumental folio volume of 550 pages, accompanied by an atlas of 64 coloured plates; and it summarized his researches, not only in Berlin, but also in Egypt, Arabia, Siberia and elsewhere. "It contained much that was new" writes Dobell, "and much that was true, everything of note that his industrious reading could find in the works of his predecessors, and withal a mass of mistakes, to which he clung tenaciously—in spite of violent contradiction and criticism—to the end of his days." This was followed in 1841 by Dujardin's great work; an octavo

volume of some 680 pages with 23 plates; and finally in 1880—1889 by Butschli's great monograph on the Protozoa. This work marks the end of protozoology as a hobby for microscopists, and the beginning of protozoology as a new science. "It is significant of the vast modern development of protozoology," writes Dobell, "that since then no work on a like scale by a single individual has been produced. It is now indeed impossible for any one man even to read all that has been written on the Protozoa, and the more recent workers have had perforce to devote their attention to some particular group of these organisms, or to some special branch of protozoology. To master a detail of the science is now the work of a lifetime. No one man can now claim to be an expert in all protozoology, any more than in all mathematics or all chemistry. The territory already surveyed was so vast that the most he could hope to do was to cultivate his own small holding properly."

From this point onwards we see protozoology studied from two main aspects; firstly as a pure science, an important branch of zoology; secondly, as an applied science, chiefly in medical and veterinary work. The importance of the former method is very great. Structurally and functionally a protozoan is the equivalent, not of a single cell of a metazoal animal, but of a whole metazoal animal itself. Dobell and O'Connor (1921) have well defined the Protozoa as non-cellular animals. Now hitherto biological study has been based almost exclusively upon the study of metazoal, i.e., cellular animals; and all the chief generalizations about such phenomena as birth, growth, development, sex, reproduction, heredity, variation and death have been based upon such study. To quote Dobell (1922a). "When the more important facts about the Protozoa are firmly established, we shall be able to recast many of our biological theorems in a more satisfactory form. The Protozoa offer us, in other words, a new world of animals for generalization, and a new standpoint from which to survey our old-world zoological knowledge. The discovery of the Protozoa was to zoology what the discovery of America was to geography. But we are still, in protozoology, in the 16th century..... As yet we are hardly on the threshold of the new biology, but for those who delight in the destruction of error and the advancement of true learning, the protozoological prospect is already full of hope."

It is with applied protozoology, however, rather than with pure protozoology that the medical man and the veterinary surgeon are concerned, and it is the evolution of this branch of the science that has now become of such fundamental importance in tropical and veterinary medicine.

The first piece of applied protozoology was Pasteur's ever famous study of pébrine. The story is of great historical interest, but I need hardly remind you of it. It is fully described in Mrs. Devonshire's translation of René Vallery-Radot's *Life of Pasteur*, and it is one which every scientific student and research worker should read. Pasteur was no protozoologist, but he laid broad and deep the foundations of modern bacteriology, and in doing so he also laid the foundations of medical protozoology. His scientific principles were impeccable, and equalled only by his own practical applications of them. In 1885 the sericultural industry of the world was faced with ruin; the silk fields of France were mortally stricken with pébrine, and even imported seed could not save them, for the infection had spread to Italy, Spain, Austria, Greece, and even China. Eggs, worms, chrysalids and moths were all infected; the peasant proprietors were in despair. J. B. Dumas appealed to Pasteur to do what he could. Although he replied that he had never handled a silkworm, Pasteur was so distressed by the sufferings of the peasants in the south of France that he immediately took up the problem.

How he solved it may be recalled in a few words. The spores of *Nosema bombycis*, the protozoal parasite that causes pébrine, are very highly refractile. And, although he did not recognize even that he was dealing with a protozoal infection, this gave Pasteur the clue to a prophylactic measure against the disease. You have a

room full of cocoons, he wrote. You want to know whether to smoothen the cocoons and spin off the silk, or to keep them for reproduction. Nothing easier. You hasten the development of about a hundred moths by elevating the temperature; these you crush in a little water and examine under the microscope for the refractile pébrine spores. If they are present, the moths are infected, their seed will be infected, and such seed must not be kept for next year's silkworms. Even if the cultivator be a peasant, he can always bottle a few of the moths in brandy and send them to a testing office or to some experienced person to examine.

It was this discovery that saved the silk industry of the world. The income to the State in the French industry, which had dropped from 130,000,000 francs a year to 8,000,000 francs, was restored; to-day pébrine still lingers to some extent in the silk fields of France, but whenever it threatens to become severe a rigorous application of the Pasteur method will always stamp it out. In India the pébrine problem is even more difficult than it is in France, since there are successive broods of silkworms in the year instead of only one; but the brilliant work of C. M. Hutchinson (1920) has shown how a more exact application of the Pasteur test may be utilized to stamp out the disease.

If the first great experiment in applied protozoology was carried out by an illustrious Frenchman, Pasteur, the second great pioneer in the same field was a Scotsman, happily to-day still with us, Sir David Bruce. By the end of the 19th century medical protozoology had become intimately linked up with another branch of zoology, viz., entomology; and to-day it is almost essential for every department of medical protozoology to have an entomological worker on its staff.

Bruce's preliminary work on nagana in Zululand was begun in 1894; but proved to be an abortive attempt. In September 1895 he resumed his study of the problem, and in May 1896 he wrote his final report on the disease at Umbobo, a report subsequently published in London in the next year. It is almost incredible that so great a discovery should have been made in so short a time. Trypanosomes had been known since 1842, if not 1841. Griffith Evans in 1880 had discovered the trypanosome which bears his name in animals infected with surra in the Punjab, and had shown that trypanosomes might be pathogenic. Theobald Smith and Kilborne in America in 1893 had shown that Texas fever of cattle, a disease due to a piroplasma, was transmitted from beast to beast by the agency of ticks. Neither of these two discoveries however is comparable to Bruce's classical work, which laid the foundation of the immense advances which were to follow.

The position when Bruce commenced his work was that there were fly belts in Zululand into which cattle could not be introduced without dying of nagana. The European settlers believed that the disease was caused by the bite of the tsetse, and Livingstone, the greatest of all African explorers, had been so impressed with the importance of the tsetse that he put a vignette of a tsetse on the title page of his *Missionary Travels*. The Zulus, however, believed that the disease was "caused by the presence of large game, the wild animals in some way contaminating the grass or drinking water." It was a stroke of genius on Bruce's part to fit these two hypotheses together and get at the truth. Within nine months he had discovered the trypanosome of nagana, which now bears his name, *Trypanosoma brucei*; had shown its presence in the blood of the wild game in the infected areas, and that it was harmless to the wild game, who are habituated to it, but pathogenic to oxen, horses, and other domestic stock introduced into the area of infection. He had discovered the transmission by Glossina, though he considered that such transmission was by direct transference on the proboscis of the fly, and had no suspicion of the cyclical development in the mid-gut and salivary glands of the insect. (It was only later, when Kleine in 1909 showed that fed flies did not become infective until the 18th to the 20th day after the feed on an infected animal, that suspicion of a cyclic development was aroused.)

Bruce's work was fundamental. "He threw a flood of light on many other protozoal diseases" writes Dobell, "and suggested all sorts of possibilities concerning their causation and prevention. He forged new links between zoology and medicine, and between entomology and protozoology..... Bruce's work was solid, complete, and demonstrative. By clean experiments and right reasoning he contributed more to science in a few months than hundreds who have followed up his work have since been able to contribute in many years. In work of this sort it is the quality, and not the quantity, that counts. Later researches have but served to enhance the magnitude and the difficulty of the problem which confronted Bruce in 1895; and to find a just parallel to the masterly manner in which he solved it, we must go back to Pasteur. There is, indeed, the same simplicity, the same directness, the same insight, in the work of both these men. Their works are enduring demonstrations of the method of science; they are a delight to read, and illustrate on every page the favourite maxim of Boerhaave: *Simplex sigillum veri.*" (Simplicity is the hall-mark of truth.)

The immediate outcome of Bruce's work was, of course, the Royal Society's Commission on Sleeping-Sickness, 1903-1913. India will always be proud that two workers from this country, Lieut.-Col. E. D. W. Greig, I.M.S. (ret'd.), and Brevet-Col. F. P. Mackie, I.M.S., shared in the work of that Commission. The work of the Commission is so well known that here it needs no recapitulation. The Commission was under the directorship of Bruce himself, and its most important discovery was the cyclic development of trypanosomes in tsetse flies, and the relationship between *T. brucei* of wild animals, nagana of domestic animals, and sleeping-sickness of man. The position in Africa to-day is still serious enough in all conscience; but, had it not been for Bruce's great discovery, and the work of the Commission, immense tracts of the African continent might to-day have become uninhabited forests in which man could not live.

The rôle of biting insects in the transmission of protozoal diseases, thus established by the work of Smith and Kilborne and that of Bruce, was soon to be further established by the labours of the third of the great pioneers, Sir Ronald Ross, again a Scotsman. I need not here discuss his wonderful discovery of the transmission of bird malaria by *Culex* mosquitoes, and its applicability to the transmission of human malaria by *Anopheles* mosquitoes. This—the greatest discovery ever made in tropical medicine—was carried out in India, its final and triumphant issue being reached in Calcutta. There had been much brilliant work done on malaria before Ross' great discovery, whilst its final and complete confirmation by the Italian workers was an essential step on the road of progress. Laveran's great discovery of the malaria parasite (November 6th, 1880) had been confirmed by Richard (1882): the complete schizogony cycle and the relationship of the parasite forms to the temperature chart had been worked out by a host of workers, notably Golgi, Marchifava, Celli, Canalis, Grassi, Feletti, Bignami, Bastianelli, Sanfelice and Manneberg. But when Ross commenced work on the sporogony cycle in 1895, nothing existed except ingenious guesses as to the truth. Of these perhaps the most important was the paper by Richard Pfeiffer (1892), who recognized the relationship of the malaria parasites to the coccidia, and predicted for the former an exogenous cycle similar to that of the coccidia, but which, owing to the absence of a resistant stage comparable with the coccidial oöcyst, he thought would be found in the body of some blood sucking insect. The resulting germ, he thought, might find its way into man through the sting of the insect. It is doubtful, however, whether Ross had ever seen this paper, for he does not mention it in his *Memoirs*. Sir Patrick Manson's association with Ross' great discovery we need not dwell on here; nor the details of the great discovery itself. It is all a matter of history, and any medical research worker who has not read Sir Ronald Ross' wonderful *Memoirs* should consider his qualifications for his appointment inadequate.

What one would like to emphasize, however, were the conditions under which Ross worked in those days in India. To-day they are almost incredible. When Ross commenced work on the transmission of malaria nothing was known about the classification of mosquitoes; he could obtain no help, even from the Indian Museum, and it was only by degrees that he realized that he was dealing with three different types; the grey or barred-back (*Culex*), the brindled type (*Aedes*), and the dappled-winged (*Anopheles*). He had to pay the entire cost of his enquiry out of his own pocket. There were no Romanowsky stains in those days, and, to judge from his *Memoirs*, almost the whole of his work was carried out by fresh dissections and studying fresh unstained material. Soon after he had started his work, he discovered the process of ex-flagellation in the mosquito; but he had no sooner made this preliminary discovery than he was transferred on special sanitary duty to Bangalore. His views on this transfer, and the interruption of his work are set forth in the *Memoirs*; "Great is Sanitation—the greatest work, except discovery, that a man can do." And in his pocket-book he wrote the following stanza:—

'We cry "God, make us Kings,
Poets or Prophets here"
The scornful answer rings,
"First be My Scavenger."'

In April 1897 after a five months' bombardment of Army Headquarters to put him on special duty for the malaria investigation, he took two months' leave, and in the rest house at Sigur Ghat discovered for the first time an *Anopheles* adult and realized that its resting attitude on the wall differed from that of the two types which he had been studying previously. It was on August the 20th, 1897, that he first found malarial oöcysts in fed *Anopheles* at Secunderabad. No sooner had he made this discovery than he was transferred on military duty first to Bombay, then to Kherwara in Rajputana, a place in which it was impossible to obtain material to continue his work. Ross heads the chapter in his *Memoirs* dealing with Kherwara "Punishment," though it is much more likely that his transfers were the result of military routine than of any intention of interfering with his work. Authority always finds it inconvenient to deal with genius; Sir Ronald could never stand either fools or authority patiently, whilst he sought, not to unravel, but to cut through red tape—an impossible procedure. It was during this interval in 1897 that MacCallum discovered the process of fertilization of *Hamaproteus columbae* of the pigeon, and that the true character of what was termed 'ex-flagellation' became clear.

Finally, however, in March 1898, Ross received at last the long awaited order, and was instructed to proceed to Calcutta for six months, during which period he was ordered to solve both the problem of malaria transmission and that of kala-azar transmission:—some order, when it is realized that the latter problem is still not finally cleared up after twenty-five years of intensive study of it by many workers in India. Even on his arrival in Calcutta, ill luck still dogged him, for cases of malaria were very difficult to secure, owing to a plague scare; and it was this that drove him to study *Plasmodium praecox* in *Culex* mosquitoes. It was in May 1898 that he sent in his ever memorable *Cultivation of Protozoa*, Labbé, in *Grey Mosquitoes* to Simla for publication. His views on the fact that it was not issued from the Government Press until October of the same year will be found in his *Memoirs*. In the meantime some thirty or forty copies had been made by hand and circulated.

If we add to all this the fact that Ross had not received any special protozoological or entomological training, as far as one can judge from his *Memoirs*, that he had to coin a new terminology for the parasite phases that he saw, one becomes even more than ever amazed at the brilliance of his work, his intuition, and his great discovery. In logical sequence Pasteur, Sir David Bruce, and Sir Ronald Ross are the great triumvirate who created medical protozoology.

Ross had predicted on the most solid grounds that the development of the human malarial parasites in *Anopheles*

mosquitoes would be found to be similar to that of *P. praecox* in *Culex* mosquitoes; but it was the Italian workers who finally demonstrated the actual transmission of human malaria from man to man by *Anopheles* mosquitoes. From that day to this the actual parts played respectively by Ross and by Grassi in the great discovery have been the subject of an endless and most acrimonious controversy. To the impartial historian of the future, one believes that the claims of both workers will be clear. There are two facts that appear to emerge from a study of the historical record. The first was that the Italian workers were familiar with Ross' work; Grassi in his first publication in October 1898 (*Policlinico*) refers directly to it, and in his second paper in November 1898 (*Lincci*) refers to Sir Patrick Manson's account of Ross' work given at the July 1898 annual meeting of the British Medical Association, and states that he had received some of Ross' proteosoma specimens and mosquitoes from Manson. On the other hand, it is abundantly clear from the record that the Italian workers, and above all Grassi—who was both a distinguished entomologist and a distinguished protozoologist—had commenced work at the problem at the same time that Ross did; and that their claim that their work was entirely independent of that by Ross is a true and legitimate one. "Grassi may have been, and probably was, influenced and guided to some extent by what he had heard of Ross' discoveries" writes Wenyon (1926, p. 910), "but nevertheless he and his co-workers were the first to obtain the absolutely scientific proof of the specific relation of anopheline mosquitoes to human malaria, and to follow the complete cycle of development of the three human malarial parasites in these mosquitoes, as Ross had done in the case of the parasite of birds." If Grassi had never published anything except his wonderful monograph of 1900, describing in detail the complete life-cycles of the human malarial parasites in anopheline mosquitoes, his claim to fame would still rest secure. As it was, he made many other important contributions both to zoology and to protozoology.

Personally, one would deplore this terrible warfare. Is it not time to bury the hatchet? The controversy has kept the Italian workers in ignorance of the huge volume of anti-malarial work which is going on in India; and the workers in India in ignorance of the work going on in Italy. To both Italy and India alike malaria is the most important problem of all; is it not time for both countries to take stock and make a friendly comparison of notes?

Whatever the true facts of the case, the conditions under which Ross suffered, and the immense difficulties which he had to encounter will never again, one hopes, face the medical research worker in India. To-day, thanks to the re-organization of the Indian Medical Research Department by the late Sir Pardey Lukis, and to the creation by Sir Leonard Rogers of the Calcutta School of Tropical Medicine conditions are utterly different; the problems are there, there is financial provision for their investigation, the only difficulty is to find men of the right type to investigate them.

If the science of medical protozoology was well established by the beginning of the 20th century, in common with many other branches of medicine and surgery, it received a great stimulus during the Great War. And here we come to further pioneer work, in this case in connection with the intestinal entamoebæ of man.

The study of these organisms goes back to the days of that wonderful pair of workers in India, Timothy Richard Lewis (1841–1886), and David Douglas Cunningham (1843–1914). Lewis was a Welshman, born in 1841, who had a most distinguished career as a student at University College and at Aberdeen. He entered the Army Medical Service in 1868, and was sent out together with D. D. Cunningham to India to investigate and report on cholera. They reached Calcutta in January 1869, and were shortly afterwards attached as "Special Assistants" to the Sanitary Commissioner with the Government of India. Together they studied cholera and other Indian diseases for about a dozen years, publishing during this time a number of important reports

on their researches. Lewis' first report (1870) deals with "the microscopic objects found in cholera evacuations," and contained the first account of the organism now known as *Entamoeba coli*. In 1882 Lewis was the first to discover the microfilariæ of *Filaria bancrofti*; whilst he also discovered the filaria of the dog, and investigated the relationship of filariasis to chyluria and elephantiasis. His most celebrated memoir, however, was that of 1878 "On the microscopic organisms found in the blood of man and animals, and their relation to disease." This gives a detailed account of the spirochaetes of relapsing fever, and the first description of the rat trypanosome which now bears his name, *Trypanosoma lewisi*. He returned to England for good in 1883, on his appointment to the post of Assistant Professor of Pathology at the Army Medical School, Netley, and unfortunately died from pneumonia, apparently contracted as an accidental laboratory infection, in 1886 at the age of only 45.

"Lewis' place in the history of tropical medicine and medical parasitology is not difficult to define," writes Dobell (1922), "He was, like Manson, a pioneer..... If Manson is the 'father of tropical medicine' then assuredly Lewis is at least its godfather; for it will not be forgotten that, in addition to his personal contributions to science, he founded both in India and at Netley, a school and a tradition whose fruits are now visible to all the world in the researches and discoveries of the officers of the Indian Medical Service and the Royal Army Medical Corps..... Lewis was an honest man and an honest worker..... He was an indefatigable worker, and as conscientious and careful in the observation of facts, as he was cautious and clear in their interpretation." And Dobell goes on to mention that shortly before his death Lewis had been recommended by the Council of the Royal Society for election to the Fellowship—an honour which he did not live to see consummated.

Concerning the career of D. D. Cunningham (1843–1914) I have been able to gather only very few particulars, and those chiefly from an obituary notice by Sir David Prain. He was a son of the Free Kirk of Scotland, and educated at Edinburgh. He entered the Indian Medical Service in 1868, went on a tour with Lewis on the continent to study mycological methods, and arrived in India with Lewis in January, 1869. Most of his service was spent in Calcutta as Professor of Physiology at the Calcutta Medical College. Although most of his publications deal with the cholera enquiry, he was essentially a worker in cryptogamic botany, and gave much valuable advice to Government with regard to cinchona plantation. One of the things for which he will always remain famous was the establishment of the small laboratory in the Calcutta Zoological Gardens, in which so many famous men have worked, but which—alas!—is to-day deserted and neglected, a most valuable field for study lost. He was also especially associated with the Indian Museum and the Asiatic Society of Bengal.

Cunningham further investigated the amœbæ which Lewis had found in cholera stools, and gave a detailed description of both the motile and the encysted phase. Dobell (1919, p. 72) quotes, exhaustively from this account, and concludes that "nobody who reads Cunningham's account and studies his pictures can fail, if he knows this organism, to recognize in them the commonest of the intestinal amœbæ of man—*Entamoeba coli*." Cunningham also gave accounts of both *Trichomonas hominis* and *Chilomastix mesnili*, but neither of them are as accurate as his account of *E. coli*. Still later he was the first person to see *Leishmania tropica*, as the colour plate illustrating his memoir, now in the museum of the Calcutta School of Tropical Medicine, clearly shows. The staining methods of those days were crude, however, and he was not able to correctly interpret the structure or morphology of these organisms, and it remained for Leishman at Netley in 1903 and independently for Donovan in Madras in the same year to give the first recognizable account of the leishmania parasites. With regard to his work on intestinal organisms, unfortunately Cunningham later was led astray by the finding of flagellate protozoa together with entamoebæ in the

same stools into ascribing all the forms which he had accurately observed and described into the life-cycle of a single suppositious organism, which he named *Protomyxomyces coprinarius*, and regarded as a sort of Mycetozoon.

"Cunningham was an able and sound scientist" writes Balfour (1925), "most accurate, honest, and careful, but with a critical faculty perhaps unduly developed..... He will always remain not only one of the leading names in the annals of the Indian Medical Service, but a pioneer to whom great credit is due for his painstaking researches." The climate of Calcutta however ruined his health and he retired as an invalid to Torquay in 1898, to devote himself to his garden, his books, and his canine friends.

Lewis and Cunningham did not name the amœbæ which they studied in Calcutta, but simply used the term 'amœbæ.' They were right in assuming that this species was in no way pathogenic. *Entamoeba histolytica* was first discovered by Lösch in 1875 in Petrograd, and he rightly regarded this species as pathogenic to man. Lösch also used no specific name for his organism; he uses the term 'Amœba coli,' non-italicized, and even then with some hesitation.

The subsequent history of the study of the entamœbæ of man has been dealt with in full detail by Dobell (1919, p. 27). It is a tale of disaster, of chaos piled on chaos, of confusion becoming worse confounded. Distinguished names occur in the record, but not much distinguished work. By 1918 *E. coli* had been described under 22 different synonyms, and *E. histolytica* under 33, and hardly a month passed without the discovery of some 'new amœba of man.' Then came the Great War. The belief by that time was universal that almost all the dysentery of the tropics was of amœbic origin, and British and Indian troops alike fighting on tropical war fronts were drenched with emetine, which was given in drastic and most dangerous doses. How many hundreds or even thousands were crippled by this 'treatment' one will never know, but one does know of army officers whose cardiac mechanism was permanently damaged by it, and who had to be invalided in consequence.

The first attempt to get matters right was made by Walker, even before the war. In 1911 Musgrave and Clegg (1904, 1906) had upheld the quaint thesis that "all amœbæ are or may become pathogenic..... The whole of the surface flora of the Philippine Islands carries a large number of these parasites. Some of them, at least, belong to the class which produces disease in human beings." Walker (1911) clearly differentiated the free-living amœbæ of the Manila water supply from the entozoic entamœbæ, showed that *E. coli* and *E. histolytica* were different species, and finally in 1913 in conjunction with Sellards experimentally proved the mode of transmission of entamœbic infections.

The war, however, made a careful study of the subject imperative, since dysentery is such an important war disease. In 1915 large numbers of troops from the eastern war areas began to arrive in Great Britain; dysentery was very rife on the Gallipoli and Egyptian fronts, and protozoological examination of an enormous number of stools was called for. This work was begun by Dr. C. M. Wenyon, but was taken over at the end of 1915 by Mr. Clifford Dobell, M.A., F.R.S., now Protistologist to the Medical Research Council of Great Britain. Dr. Wenyon was transferred to Alexandria, where, in conjunction with Dr. F. W. O'Connor, he commenced similar investigations on troops from the Gallipoli, Salonika, and Palestine fronts.

The results of these researches were, and are to-day, of fundamental importance. In 1917 there was published Wenyon and O'Connor's *Human Intestinal Protozoa in the Near East*, a most valuable, though perhaps slightly incomplete, work. Then in 1919 came Dobell's great work, *The Amœbæ living in Man*.

The Amœbæ living in Man is characteristic of all Mr. Dobell's work. It is no hurried or sketchy compilation, but the result of intense and extensive personal work of the very highest order, of mature thought and reflection. Its contents cannot be assimilated at a single

reading; it is a book to study again and again and again; also it is full of most valuable practical laboratory instructions, and based upon very extensive personal investigation. It was followed in 1921 by a second, excellent work, Dobell and O'Connor's *The Intestinal Protozoa of Man*. To the student in India who wishes to familiarize himself with the intestinal protozoa of man, the best advice that one can give is to study these two books again and again, and to constantly examine the stools of sweepers, who, from the nature of their duties, sooner or later pick up most of the infections concerned.

As will be seen, our knowledge of the blood-inhabiting protozoa of man had been built up by degrees; whilst the war work cleared up the confusion with regard to the intestinal protozoa of man. It is probable that by now all, or almost all, of the human protozoal parasites are known. It is time to mention the question of literature and textbooks. Doflein's great work, *Lehrbuch der Protozoenkunde*, was first published in 1901, but was available only to students who could read German. It was followed by Minchin's *Introduction to the Study of the Protozoa* in 1912. Edward Alfred Minchin (1866—1915) may, indeed, be said to have been the founder of the British school of protozoology. Essentially a cytologist and zoologist, Minchin was a master of technique. For many years he was Assistant to Sir Edwin Ray Lankester and Demonstrator in Comparative Anatomy at Oxford, during which period he published brilliant and valuable work on the sponges. In 1905 he joined the Sleeping-Sickness Commission in Uganda, where his knowledge of insect anatomy and dissection were invaluable to the Commission, and where, with Gray and Tulloch he discovered the occurrence of wild trypanosomes (*T. grayi*) in the tsetse, which the recent work of Hoare (1929) has now shown to be an evolutionary stage of *T. kochi* of the crocodile. In 1906 he was appointed to the then newly-established Professorship of Protozoology in the University of London, tenable at the Lister Institute, from which Institute he published a series of ever memorable papers, dealing chiefly with the life history of the trypanosomes, and the inter-relationships of the Hæmosporidiidea. His *Introduction to the Study of the Protozoa*, however, was his most notable contribution to science. For many years it was the constant and familiar companion of those of us who were trying to teach ourselves a little protozoology. Finally, in 1926, came Wenyon's sumptuous *Protozoology, a manual for medical men, veterinarians, and zoologists* in two volumes. It has been followed by several smaller works. In 1923 there was no textbook of medical protozoology in the English language; to-day perhaps there are too many. That alone shows how rapid has been the progress of the science.

I have attempted, gentlemen, to sketch as briefly as I could, the amazing and rapid growth of medical protozoology, almost the newest and latest of the medical sciences to evolve. There are dozens of other names which I should have mentioned, other discoveries of importance, whilst I am incompetent to touch upon the allied development of the science of pure protozoology itself. In connection with India, there are two other names, however, which I cannot pass over. The first is that of Vandyke Carter (1831—1897), who discovered the Indian strain of the spirochæte of relapsing fever, and proved its infectiousness by experiments upon himself: he also described the organism of rat-bite fever in the rat, and correctly concluded that this organism is a Spirillum and not a spirochæte. The second is that of Sir Leonard Rogers, who, when he succeeded in 1904 in cultivating *Leishmania donovani* in vitro, was the first worker to cultivate a protozoal parasite on artificial media. That discovery was the precursor of much work of very great value; to-day, in my own department, for example, the routine diagnosis of kala-azar, of malaria, of infections with intestinal entamœbæ and flagellate protozoa, is carried out very largely by cultural methods.

Let me, however, gentlemen, draw my moral and conclude my tale. Medical protozoology has been very largely built up by medical men with no zoological training, and it has suffered in consequence. The 'student

mind' is not given to everyone, whilst the critical spirit is still more rare, and the untrained and ill-informed tyro does not hesitate to rush into print. Errors and dogmas have been laid down, which it has taken many years of careful work and patient observation to correct.

Yet the importance of medical protozoology in the practice of medicine in the tropics is very great. Now, what is the position with regard to the medical curricula in the different universities of India? In my opinion the syllabuses in pathology in India everywhere pay too much attention to morbid histology, and far too little to parasitology. The practising physician in India does not need to be able to diagnose an osteo-chondro-sarcoma microscopically; he can send a portion of the growth to a laboratory expert for diagnosis. But if he has not been trained in microscopical technique, if he cannot identify a malaria parasite, or differentiate between the different entamoebæ living in the intestinal tract of man, his work will be shoddy and sterile. He may commence his professional career as a physician, i.e., one who does his best to diagnose the disease from which his patient is suffering, and to treat it appropriately; no matter how much money he makes, nor how many honours descend upon him, he will end it as a quack, content merely to treat different *sympptoms* as they appear, and to leave the issue to the healing hand of Nature.

"As a profession" writes Dobell, "protozoology still hardly exists..... But the science has now become so vast, from the amassing myriads of complicated details, that it can no longer be regarded as an occupation for anyone but a highly trained specialist. The amateur toying with his microscope, the ordinary zoologist or physician working in occasional vacations or leisure hours snatched from practice, can no longer be expected to make any solid contributions to protozoology. In future all great advances in knowledge must come from those who are bred up as protozoologists..... Unless the protozoologists can build solidly, and not too slowly, they will lose their advantages. Unfortunately, no adequate provision has yet been made for the training of workers in protozoology. At present there are in Britain and elsewhere few first-rate professional protozoologists, and few competent teachers, but a large number of day labourers and dabblers from other sciences. Protozoologists are still mainly recruited from other professions. The remedy for this state of affairs will be found only when protozoology is recognized as a separate science—an occupation for specialists and not for smatterers; and when encouragement is given to its development by the founding of professorships in the subject—or similar appointments—in the larger universities. These professorships must be primarily for research, and secondarily for teaching purposes. The professor must have ample time and funds for teaching himself, and for carrying out his own researches. If he is sufficiently gifted to do both these things, he will be able at the same time to teach his science to others who will follow in his footsteps. But the time has now gone by when the junior demonstrator in zoology, or the lecturer in general parasitology in the medical schools can expect to 'take up' protozoology for a term or two and thereby profit science or himself."

I do not suggest that medical protozoology should be added as a separate subject to the already overloaded medical curriculum in the Indian universities, but the time has come when the important protozoological discoveries of the present and of the past should be incorporated in the general practice and teaching of medicine in India. The medical student should be taught more parasitology, and, perhaps, less morbid histology.

One further remark, and I have done. The day of the great pioneers is over; the field has been so well reaped that the first harvest has been garnered. But there remain for solution an immense number of more detailed problems. These call for team work; the medical protozoologist can no longer enter his laboratory and lock its door. He may require at any moment the co-operation of the entomologist, the bacteriologist, the chemist, and—above all—the biochemist, the last-named species of individual being one whom all directors of major

laboratories dream about, but rarely or never succeed in obtaining. Where are the workers in this subject coming from in India, unless we envisage the problems ahead and train men for these duties? We, in India, have a tradition to uphold. Let us attempt to live up to it.

AN ACCOUNT OF A BRIEF TOUR WITH THE MALARIA COMMISSION OF THE LEAGUE OF NATIONS.

By R. KNOWLES,

LIEUTENANT-COLONEL, I.M.S.,

Professor of Protozoology, Calcutta School of Tropical Medicine.

It may be of interest to readers of the *Gazette* to know something of the methods of work of the Malaria Commission of the League of Nations which so recently toured India, since there are many lessons with regard to malaria control to be learnt. Thanks to the courtesy of Mr. Senior-White, Malariologist to the Bengal-Nagpur Railway, and of the Bengal-Nagpur Railway, the writer was permitted to accompany the Commission on their tour of the Singhbhum district, 28th to 31st October, 1929, and saw much that opened his eyes as to the reality and problems of malaria control in one of the most hyperendemic areas in India.

The Commission arrived in Calcutta on 23rd October, 1929. Thursday, 24th October, was devoted to the Calcutta School of Tropical Medicine. In the writer's laboratory what appeared to impress the Commission most was that the routine diagnosis of malaria is here being carried out by cultural methods, an advance even upon the study of thick films, and a valuable method for ascertaining whether the patient has or has not been freed from all parasite infestation as the result of treatment. In Dr. Strickland's laboratory the methods of malaria control in the Duars and in Assam were shown; in Colonel Lloyd's laboratory the results of a study of the changes in the serum proteins in malaria—an investigation of great importance, since its bearing on methods of diagnosis and treatment is obvious. Mr. M. O. T. Iyengar also gave a splendid exhibit of the very important work which he is doing in the study of the anophelines of Bengal, their breeding habits, seasonal variations, and the natural parasites of anopheles. In the afternoon a conversazione was held at the School for the purpose of enabling the members of

the medical profession in Calcutta to meet the members of the Commission. On Friday morning, 25th October, Mr. Senior-White and the writer laid before the Commission the results of their studies of the geographical and seasonal distribution of species of malaria parasites, with special reference to the work carried out in India during the present century, and also discussed the future problems in malaria awaiting investigation. Each member of the Commission was presented with a typed copy of the 120 pp. of the manuscript dealing with India, and a copy of the new India map, 4 by 3 feet, showing the distribution of parasite species in man in India. A discussion ensued in which Dr. Bentley and Colonel Acton took part, and the discussion was then adjourned until the party should re-assemble in the train. The afternoon was devoted to seeing the work of the Anti-Malaria Co-operative Society in Bengal.

The party re-assembled at Howrah station at 4 p.m. on Monday, 28th October, in time to catch the Bengal-

The members of the Malaria Commission of the League of Nations.

Reading from left to right they are:—

- Dr. Louis Williams (United States).
- Professor de Buen (Spain).
- Dr. Peltier (France).
- Professor Swellengrebel (Holland).
- Professor Schüffner (Holland).
- Professor Cuicá (Rumania).

Nagpur Railway Bombay mail. It consisted of the following members of the Commission:—

- Professor Schüffner (Holland).
- Professor Swellengrebel (Holland).
- Professor de Buen (Spain).
- Professor Cuicá (Rumania).
- Dr. Peltier (France).
- Dr. Louis Williams (United States).
- Major J. A. Sinton, V.C., I.M.S.

Mr. R. Senior-White, F.R.S.E., Malariologist, Bengal-Nagpur Railway, was in charge of the tour. In addition, the following also accompanied the party:—

Lieut.-Col. J. A. S. Phillips, I.M.S., Director of Public Health, Bihar and Orissa.

Dr. R. N. O. Moynan, Medical Officer, Adra, Bengal-Nagpur Railway (who joined at Amda).

Mr. G. Fitzgerald, Assistant Transportation Officer Bengal-Nagpur Railway (who joined at Dangoaposi) and the writer.

The party was accommodated in a saloon tourist car attached to the end of the Bombay mail.

At this point, one would like to pay a tribute to the most admirable arrangements made throughout the tour

by the authorities of the Bengal-Nagpur Railway. The programme was carried through without a hitch, and in absolute comfort. Every possible arrangement had been made beforehand; the catering was admirable, excellent meals being served in the dining car in the most outlandish places, and a special word of praise is due to Mr. Fitzgerald for his powers of organization, and of dealing with any emergency. The writer must confess that the trip has thoroughly spoilt him as regards travel as an ordinary passenger.

The saloon car had a drawing room with comfortable accommodation for 12 at a central table, and, as we ran out of Howrah station each member of the party was presented by Mr. Senior-White with a most elaborately prepared file of 18 documents, maps, etc., dealing with the tour. He first drew our attention to the spleen index malaria map of India drawn by Christophers and Sinton, of which each of us was presented with a copy. On this map was superimposed the Bengal-Nagpur Railway system. The result was extremely striking; there can be no doubt that the Bengal-Nagpur Railway system traverses the most intensely malarious tract of India, and the need for a special malariologist for this railway, and of the utmost efforts to deal with the disease was very obvious. As we ran through the water-logged tract of Santragachi, Mr. Senior-White explained that here the spleen rate is under 10 per cent (including both that due to malaria and to kala-azar), but the sick pay loss to the railway from malaria at this station is more than Rs. 5,000 a year. Here the anopheline breeding-sites shift about, and until the introduction of Paris green control appeared impossible, but thanks to this substance something may be possible in the future when considerations of finance enable this station to be taken up. Everywhere throughout the area from Howrah to Santragachi are better class Bengali houses lying deserted; partly this is due to the natural tendency towards migration into Calcutta city, partly to malaria, partly to kala-azar. Generally, in this area the railway simply has to put up with malaria as something which cannot be controlled by present day methods. The situation is part of the general Bengal malaria problem, and cries out for intensive research.

Conversation being nearly impossible owing to the noise of the train, the members of the party were next left to digest the information in the voluminous file presented to each of them, the various points in which were explained by Mr. Senior-White to different members of the party in turn. Amda junction was reached after dinner, and here the saloon car was detached from the Bombay mail, and a special train made up. This consisted of a dining car, the saloon tourist car for the Commission, Mr. Senior-White's saloon, Dr. Moynan's saloon, and a third class carriage for servants. This was attached to a goods train for Dangoaposi. (At 10-30 p.m. we struck something with a bang—probably a wandering cow—but it did not disturb the serenity of the goods train!)

Tuesday, 29th October.—The train reached Dangoaposi station at 5 a.m. and Mr. Fitzgerald's saloon was attached, also a brake van. We were now detached from the goods train, given an engine to ourselves, and became a "special."

The real interest of the tour now commenced. We were moving through intensely picturesque country, forested hills arising from richly fertile plains largely covered with paddy, intersected by streams—"Derbyshire-like" country, in fact. To the eye of the uninitiated this country would appear to be of the nature of a health resort. Actually, it is a death trap. During the railway construction a semi-permanent camp was erected on the summit of a low, forest-clad hill, in a most picturesque spot. But at the foot of the hill incessant seepage led to intensive anopheline breeding—chiefly *A. funestus*; within half a mile of the newly constructed bungalows for the staff was an aboriginal village whose inhabitants were drenched with malaria. Blackwater fever and malignant tertian malaria ravaged the engineering staff; the camp had to be abandoned as the future site of an important station, and a new site selected.

Passing through Noamundi, we were again shown country where malaria control is financially impossible. On either side of the line rice fields stretch for miles, and are fed by springs from the low hills, which arise in a multitude of places in the paddy land. The station staff at Noamundi consists of two Indian officials and six aboriginal menials. To attempt control of this area would be immensely expensive, and the proposition is not worth it. Infection of running train crews in this area is avoided by keeping the trains conveying the iron and manganese ore up at the mine heads in protectable and protected areas until they can get a clear run through Noamundi station, especially at night.

We now entered on the steepest gradients on the whole Bengal-Nagpur Railway system, approaching Messrs. Tata's iron mines at Noamundi. The soil practically consists of pure iron ore, and the railway cuttings run through what is almost pure ironstone. The mineral wealth is here so rich that ore which would be worked for all it is worth in Europe is discarded, and only the purest ores, which are almost pure Fe_2O_3 , are worked. The train now stopped and we were met by Mr. G. G. Dobbs, the Chief Superintendent of the mines; the Resident Manager, Mr. Maitra; Dr. Sen, the Assistant Medical Officer to the mine; and Mr. Roy, B.Sc., the Malaria Inspector.

Fig. 1.—The special train for the League of Nations' Malaria Commission on the Bengal-Nagpur Railway, at Dangoaposi Station.

Malaria control at Noamundi mine is something which must be seen to be believed. One doubts whether even in far-famed Panama there is anything like it; it is probably one of the most complete and perfect schemes of control anywhere in the world. It is in charge of Mr. Roy, a B.Sc. in engineering, with an unlimited labour staff to help him, and as much dynamite as he requires.

We were led first to the superintendent's office. On the wall of this office hangs a large blue print map, 5 by 4 feet in area. On it is marked every spot that requires oiling; S.W. for standing water; S.P. for seepage; R.W. for running water. Taking the power house and the dak bungalow as the two main foci at different ends of the mine an ellipse has been drawn with a half mile radius around these foci. Within this area control is absolutely perfect. At every point on the map where spots for oiling are marked a bone disc is hung showing the next date when the spot should be oiled. When it has been oiled the date is entered on the disc, and it is the duty of the malaria inspector to see that the spot has been oiled on the date in question.

Control was first initiated here in July, 1929. The mine was surveyed by Sir Malcolm Watson with Mr. Senior-White as a preliminary measure in March, 1929. At that time the spleen rate was 58 per cent. amongst aboriginal children, and 40 per cent. amongst the children of imported superior Bengali families. At Noamundi railway station it is 83 per cent. amongst aboriginal children. The anophelines found breeding were *A. culicifacies*, *maculatus*, *funestus*, *karwari*, and *jeyporiensis*. The

problem to be faced, therefore, in the malaria season of 1929 was no inconsiderable one.

The word 'mine' is rather a misnomer for Noamundi iron mine, for the ore is quarried from the hillside, and the area consists of several densely forested hills with valleys and ravines between. The chief source of anopheline breeding was the bed of the Kurta river which traverses the entire length of the estate from one end to the other, fed by innumerable seepages, and running in a boulder-strewn bed. This river has been trained throughout the entire longitudinal axis of the protected area. On the side where heavy monsoon rain is most likely to scour out the ravines and destroy the trained bed of the river, protective masonry walls have been built. Every seepage has been sub-soiled. And "sub-soiling" means something at Noamundi mine. It means constructing a channel some five feet deep and three feet wide, filled with rocky boulders, and covered in with graded stones and finally earth; also all trees with four feet of the drain are dug out. Dynamite has to be used freely, for the soil is practically pure iron ore. But labour is unlimited, though only a qualified engineer could have carried the scheme through. In one place there was a bad seepage down three sides of a hill enclosing a shallow valley; at an expenditure of Rs. 12,000 the entire hillside has been sub-soiled, and a cement edged reservoir constructed at the foot of the hill. A second large seepage also cost about the same sum to deal with. Everywhere seepage water has been led underground and delivered into the main stream by a protected outlet. In every spot where standing pools may be left by the river, and along its margins, oiling is practised. On the reverse side of a big hill looking away from the main river bed a large hillside has had to be dealt with. Channels have been dynamited and cut, and the entire hillside drained dry of water.

The malariologist often dreams of the ideal example of "a malaria-free enclave within a malaria-ridden district." At Noamundi mine, this ideal is realized. Dr. Williams, one of the most active members of the Commission, spent the entire morning of five hours trying to find mosquito larvæ; his only catch during this period was a single Chironomid larva. Noamundi mine is now entirely free from both larval and adult anophelines, and the only cases of malaria which occur are relapses. The chief problem remaining is a village of aborigines and contractors' labour just outside one end of the protected elliptical area, on the banks of the Kurta river. Here there is free anopheline breeding and an intense malaria incidence. The question is whether this village will act as an anti-malarial screen for the protected area, or whether it is a danger focus. Opinions expressed by different members of the party differed on this point.

In addition to malarial engineering on this estate, it may be added that all residential bungalows are screened. The labour population consists very largely of aboriginal Hos, Sonthals, Tantis, and the like, and at the mine hospital Professors Schüffner and Swellengrebel carried out an investigation into the adult spleen rate in these tribes.

What malaria control costs at Noamundi mine, one did not enquire. It was obvious that such principles are only applicable by some of the wealthiest commercial concerns in India. What the Commission thought of it, we shall know when their report is published. It is significant, however, that there were 18 cases of blackwater fever on this mine in 1928; there have been none since the control commenced.

The special now returned to Dangoaposi station, and after tiffin Mr. Senior-White demonstrated to us the malaria control at this station.

Here conditions are utterly different from those at Noamundi mine. In the first place there is, relatively speaking, no money at all; hence anti-malaria measures have to be of the cheapest kind. Yet the position here is an extremely serious one. At Dangoaposi station the entire traffic from the iron and manganese mines above is marshalled, goods trains are made up for transit to Messrs. Tata's huge iron works at Jamshedpur, and the Indian Iron and Steel Coy. at Burnpore, and—in

connection with the manganese industry—for transit to the coast for loading on sea-going vessels for transshipment overseas. The entire population at Dangoaposi station only consists of some 240 persons employed by the railway, with about the same number of dependents; but the station handles approximately half a million sterling's worth of goods traffic a year, and hence malaria control is here imperative.

Malaria at Dangoaposi railway station is almost entirely man made (as it is in the majority of malarious areas in India). Here the railway cuts through a cutting with steep banks from which seepage incessantly accumulates in borrow pits by the side of the line. On one side of the line rice fields stretch away to the nearby foothills. To one side of the line the railway engineers had dug a lengthy storm water channel, badly constructed, and an incessant source of anopheline breeding. Matters were so bad that in September, 1925, before control was started, the incidence of malarial attacks among the running employees was 287 per cent. for that month; i.e., each employee had approximately three attacks of malaria during that month. Engines lay idle on various sidings since there was no one well enough to drive them, and the mineral traffic was almost at a standstill. Control was commenced, on the appointment of Mr. Senior-White as Malariologist to the railway, in November, 1925.

An interesting point about Dangoaposi station is that Mr. Senior-White has here found spleen rates in children of no value as an index to the intensity of malaria in railway employees. The employees enjoy the right of free railway passes for themselves and their families; hence the child community is constantly altering, families being brought into the station and others sent to their homes elsewhere. It has been found at Dangoaposi that case incidence in employees alone is of value in railway work.

For malaria control at Dangoaposi, Sub-Assistant Surgeon B. M. Swami, the only medical officer in the place, receives an extra allowance of Rs. 10 p. m. over and above his pay. He has also the services of one gang mate at Rs. 17 p.m., and of six coolies, each at Rs. 15 p.m. One can here only simply congratulate Dr. Swami on the magnificent results accomplished with so small a staff. His work is typical of the quiet, unostentatious work in malaria control which is going on all over India, but whose existence is hardly ever recognised.

Only two main measures are possible at Dangoaposi. Swamps and borrow pits have been filled up with waste ash from engines, the borrow pits on the two sides of the line being connected together, and a flowing channel created. The storm-water channel has had to be re-dug throughout and trained for a distance of a mile or more.

Taking the usual half mile radius from the residential station quarters, complete protection has been afforded by these measures, and by regular oiling. The work is incessantly and systematically carried out, and frequently supervised. Mr. Senior-White indeed informed us that Dangoaposi was called his "spiritual home." Taking the most intensely malarious months of the year, the results have been as shown on the following page.

Apart from the cost of the share of the salary of the malariologist to the railway, the entire cost of the operations at Dangoaposi station works out at Rs. 2,353 per annum, or about Rs. 6 per head per annum of the population resident in the station and railway quarters. How severe malaria is in the unprotected stretch of the railway in this area may be gathered from the fact that, during the few days that the Commission was on tour in it, the death of one railway guard from blackwater fever was reported, and the occurrence of three severe attacks of malignant tertian malaria amongst others. Dr. Moylan, who accompanied the party, also suffered from a very severe attack of malignant tertian malaria during the tour, contracted somewhere on his district, which includes all the hyperendemic area of Chota Nagpur.

Dangoaposi station presents a malaria control almost as perfect as that at Noamundi mine, but at absolutely

Year and month.		Incidence of malaria per cent. of running staff.	Residents.
September, 1925	Before control.	287	62
October, 1926	After control.	79	4
October, 1927	During this year Mr. Senior-White was at Delhi, and the B. N. Ry. was without a malarialogist.	207	39
September, 1928		27	10
October, 1929		8	5

minimal cost. It is obvious, however, that at the former place incessant vigilance has to be exercised, for any falling off in the control will immediately be accompanied by a wave of epidemic malaria. What little residual malaria remains is due to anophelines from outside the controlled area, i.e., from the vast area of rice fields around the station. These could not be controlled, except at prohibitive cost; probably dusting of Paris green from an aeroplane would be necessary. In passing, it is of interest to note that Mr. Senior-White has decided to neglect *A. fuliginosus* altogether; it is a frequent breeder in rice fields, but appears to be without danger.

The moral of Dangoaposi station is, we believe, applicable to vast tracts in India, and especially to big commercial concerns in India. The members of the Commission did their best to find a mosquito larva in the controlled area, but failed. Professor Swellengrebel, with the true critical spirit of the research worker, then demanded to be led outside the controlled area; he discovered anopheline larvæ immediately.

On returning to the train, and after tea, discussion of the paper by Mr. Senior-White and the present writer was resumed. The "attack" opened as one had expected it to. Despite the fact that the authors had done their best to search the entire literature locally available on the subject during the present century, every member of the Commission present complained that no end of important papers and reports from his country had been overlooked. (This is inevitable; the resources at our disposal were limited; and the memoir—if it ever sees publication—is intended as something basic on which it is hoped that others will build; a first attempt, rather than a complete exposition, which we know to be impossible.) Extraordinary differences of opinion developed during the discussion. Thus some workers regarded Leishman's stain as invaluable in the diagnosis of malaria, others regarded it as entirely unreliable. There was complete unanimity on one point; that the work by Jancsó in 1904 on the limitations which different degrees of atmospheric temperature and humidity exert upon the transmission of malaria by *Anopheles* mosquitoes needs complete re-investigation with reference to different countries in the tropics which is urgently necessary. Ultra-important as Jancsó's fundamental experiments are, yet they refer to only one species of *Anopheles*—*A. maculipennis*, studied at only one season of the year, and under European conditions. His conclusions do not necessarily hold true for the many different carrying species of *Anopheles* in different tropical countries.

The stimulus of such discussion of malaria problems with research workers in malaria from several different countries does not need emphasis. One learnt at every stage of the discussion. New view-points were constantly

arising, and the lesson was driven home on one more and more that malaria is an international problem, and that for its control international programmes have to be devised.

Wednesday, 30th October.—The special train moved at dawn from the siding at Dangoaposi station to Bāra Jamda. This permitted Professors Schüffner and Swellengrebel to visit Jamda village, and again examine adult aborigines with reference to their spleen rate. (The point which these two workers were investigating, especially, as far as one could ascertain, was whether the spleen rate among adult aborigines does or does not differ as markedly as it is popularly supposed to do from the spleen rate among aboriginal children.)

The train then moved on again, and at 8-30 a.m. we arrived at Messrs. Bird and Co.'s manganese mine at Uluburu. Here we were met by Captain Duxberry, the Manager; Dr. Sircar, the Medical Officer; and Mr. B. S. Mathur, the Malaria Inspector. (Mr. Mathur is one of the pupils from Lieut.-Col. Dunn's training school in the United Provinces, and one can only say that his work at Uluburu is worthy of that school.) The staff which Dr. Sircar and Mr. Mathur have for malaria control in this mine consists only of one mate and six coolies, nothing more can be afforded.

Here, again, the main malaria problem centred around a river which runs through the estate. There were 3 cases of blackwater fever (among the staff) in 1925; 3 in 1926; 2 in 1927; and 1 in 1928. As at Noamundi, here again, a main stream runs through the estate, and surveys by Mr. Senior-White in April and September 1928, had shown *A. culicifacies*, *funestus*, *maculatus*, *barbistris*, *karwari*, *fuliginosus* and *theobaldi* breeding in its pools. Again, control within a half mile radius was instituted at the commencement of the present season.

Here one of the chief solutions to the problem of anopheline control in the stream is a matter of applied hydraulics; labour cannot be spared to fill the marginal swamps which are breeding carrier species, but mining debris is shovelled into the main stream when it is in flood and this is allowed to percolate into the breeding areas concerned, the stream being diverted from the main channel where necessary. Oiling of course is also resorted to, as necessary.

Finally, we came to one of the world's mine wonders, "J. S. quarry," or—as one would prefer to term it—"Larvicide Lake." This is a disused manganese quarry which has filled up with rain water and seepage into a medium sized lake. *Its water is absolutely inhibitory to the breeding of mosquito larvæ; they simply cannot live in it.*

Larvicide Lake presents a problem for malaria workers throughout the world, and it is no wonder that it held the members of the Commission spell-bound. Its

Fig. 2.—Larvicide Lake, with the members of the Malaria Commission in the foreground.

banks are the edges of the old manganese quarry. There is a slight growth of grass at its edges, but little vegetation. There are numerous fish in the water, but

not apparently especially larvæ eating fish. Yet this water will not allow mosquito larvæ to breed in it; it is in brief Nature's own cure for the malaria problem. Experiments have been carried out in shallow pools with this water; grass and algæ were introduced and Anopheles females allowed to deposit their eggs. When so exposed to the rain and air this water retains its larvicidal properties for three weeks, but not for four weeks; at the fourth week of exposure breeding commences, but not before. At the shallow end of the lake, where the water is diluted with recent rainfall, a little breeding of larvæ may occur, but never at its deeper end. Further, the water of this lake is periodically pumped into the main stream and apparently immediately sterilises it of mosquito larvæ.

Chemical examination of the water of this lake reveals nothing of special importance. The Chemical Research Department of Messrs. Bird and Co. report that the most probable constituents of the mineral matter contained are as follows:—

Calcium carbonate	..	4.00	parts per 100,000
Magnesium carbonate	..	2.69	" "
Sodium chloride	..	1.31	" "

"In addition to this, the water contains 1.614 parts of suspended solid per 100,000 parts of water. This solid matter contains 10 per cent. of ferric iron. We cannot see how by any stretch of the imagination, these minute quantities of mineral salts—commonly present in river and spring waters in much greater amounts—can have any effect on mosquito larvæ. The ferrous iron and manganese together total less than 5 parts in every 100 million parts of water; they cannot possibly have any influence on mosquito life."

In spite of the research chemists, however, Larvicide Lake remains a reality. Here is this extraordinary lake whose waters prevent mosquito breeding. Possibly its existence may be of interest to the Indian Research Fund Association. No algæ were observed in the water, but its larvicidal action is apparently not dependent upon depriving the larvæ of this means of nutrition, for when the water is admitted into the stream below swarming with mosquito larvæ, it immediately clears out all larval breeding.

A thorough examination of water within the control area at Uluburu in September 1929, three months after control commenced, showed that breeding had been entirely eliminated, only four larvæ in one small spot missed by the oil being found. It is not easy to present results in figures, as coolies from other and unprotected camps are scheduled to the two hospitals, but it is significant that in 1929 there have been no cases of blackwater fever, and little trouble from malaria in the clerical staff at Uluburu.

At the hospital at Uluburu an interesting case of "Sarandha ulcer" was exhibited. This resembles Naga sore, or ulcus tropicum, but there is no foetid odour accompanying the discharge. Professor Schüffner took films from the sore for subsequent examination.

We next enjoyed Captain and Mrs. Duxberry's most welcome "liquid" hospitality, then walked back to the special train, and now commenced a very slow journey to Barabil station, en route the train being slowed down to four miles an hour to permit us to see the local conditions. The Uluburu river here spreads out into a wide stretch of rice land without a regular channel, overflowing which it runs through the railway borrow pits in twin streams. The mining camp unfortunately located along the hillfoot here is not economically protectable, and the only solution possible will be to close the existing camp and move it to a protectable area some way on at the end of the branch line.

At Barabil the party divided into sections. Professors Swellengrebel and Cuicá investigated the spleen index among adult aboriginal women who were attending the weekly market at Barabil, which happened to be in progress. Professor de Buen, with Lieut.-Col. J. A. S. Phillips, I.M.S., Dr. Moynan and the present writer went off in a Chevrolet over 7 miles of jungle road to investigate conditions in a completely uncontrolled area.

Drs. Schüffner, Peltier, Williams, and Major Sinton stayed behind to see a demonstration of how a stream running through swamp land can be made to cut a bed for itself, and so dry the swamp.

The party re-assembled at 1 p.m., and the carriages were attached in turn to the passenger train from Bara Jamda to Amda, run again as a special to Tatanagar, and were then attached to the Ranchi express, and reached Howrah station at daylight on Thursday the 31st October, 1928.

During the afternoon of the 30th a full discussion of what had been seen during the tour took place. Dr. Williams stated how gratified he was at all that had been done to ensure the comfort of the Commission, and how impressed they had been with what they had seen. A controversial attitude was assumed quite early in the discussion by Professors Schüffner and Swellengrebel, who stated that they regarded malaria as more than a 100 per cent. spleen rate as concluded therefore that malaria in its most intensely hyper-endemic areas in India could not compare with conditions in the Dutch East Indies. Further, Professor Swellengrebel considered that control within a half mile radius of the area concerned was quite inadequate. Here he was interrupted by Dr. Williams, who stated that in the Southern United States they had started with the idea of control within a radius of one mile, had reduced it to three-quarters of a mile, then to a radius of half a mile, and had found results to be equally good in most cases.

Professor Swellengrebel however considered that the range of flight of malaria-carrying anophelines in India appeared to be remarkably less than in the Dutch East Indies. At this point, Mr. Senior-White explained that, with regard to malaria control on railways in India, what was to be aimed at was what was practicable, with regard to the meagre funds available, rather than what was ideal. A half mile radius may be relatively inexpensive, but if a one mile radius is to be insisted on, the proposition may be beyond the realm of the practicable; funds will simply not permit it. He considered that the actual working examples which he had shown the Commission of practical control within a half mile radius proved his point that such control was both reasonably efficient and reasonably cheap.

Finally, some difference of opinion was expressed with regard to the breeding places of *A. culicifacies*. Mr. Senior-White pointed out that this species, if hunted, can take refuge in the usual breeding sites of *A. rossii*, and thus complicate the problem to an extent not realized by workers from the Further East, who have not this species to combat.

The discussion carried us through till dinner time, and Tatanagar was reached shortly afterwards. The saloon cars were here attached to the end of the Ranchi express, and Howrah station was reached at 5-30 a.m. on the morning of the 31st. The saloon cars were here detached and run into a siding to allow everyone to dress at leisure.

* * * * *

The programme which the Commission carried through during their tour of nearly five months in India was a very strenuous one. India is accustomed to cold weather visits by Commissions; but a Commission which comes out to study malaria in India during the actual malaria season, and visits the most intensely malarious tracts in this country, not without some risk of malaria to the members of the party, is a novelty. It will be seen how many problems with reference to malaria control were raised in this one short trip alone. What impressed the writer more than anything else during the tour was the invaluable opportunity which it afforded for workers in India to compare notes with workers from other tropical countries, and the stimulus of the discussions.

Malaria is an international tropical disease. One hopes that this first visit of the Commission to India is but the initial stage towards the evolution of an international organization under the League of Nations for malaria control.

JANUARY.

THE USES AND ABUSES OF VACCINES.

ALTHOUGH the theoretical justification for the employment of vaccines is dependent on the work of Pasteur and his immediate successors, the practice of preventive inoculations has been in existence for many centuries amongst the members of earlier civilizations and even amongst primitive peoples. The earliest practice of vaccination consisted in giving the disease itself to a healthy person at a suitable age period or on some suitable site in order to obviate subsequent infection at a more susceptible age or on some part of the body which would cause disfiguration; examples of these practices are the habit of placing young children in contact with others suffering from small-pox and the inoculation of oriental sore on some covered part of the body. The next step was the inoculation of a living attenuated virus, examples of which are cow-pox and the fixed virus of rabies. Both these inoculations protect against the disease produced by the fully virulent organism.

It was some years after Pasteur's discovery that the injection of not only living but dead cultures of bacteria would protect an animal against the effects of subsequent inoculation by a living culture of the same organism that vaccines came into general use as prophylactic and therapeutic agents. Following up the work of Koch, Sir Almroth Wright introduced the smaller, controlled dosage with tuberculin and later anti-typhoid inoculation, and, although his method of controlling the dosage by means of the opsonic index has now fallen into disuse, it can be said quite truly that he was mainly responsible for "popularizing" vaccine therapy.

Though for many years prior to 1914 vaccination had been employed as a public health measure, the War gave a great stimulus to preventive inoculation against other diseases, and towards the end of 1918 almost every soldier in each fighting force had been inoculated against enteric and small-pox, and, for those stationed in tropical areas one must add, plague and cholera. This, so to speak, broke the ice, and it is now a common incident for large civil populations not only to submit, but actually to clamour for wholesale inoculation. The use of vaccines as a therapeutic measure has now ceased to be a novelty, and has passed out of the hands of the specialist and bacteriologist into those of the general practitioner and manufacturing chemist. That the reputation of vaccine therapy has suffered from this change of control it is needless to say, and to-day there is a feeling amongst certain practitioners that vaccine therapy is a passing fashion which will soon be condemned to oblivion. In this opinion they are just as wrong as their fellow practitioners, and possibly

they themselves a few years earlier, who hailed vaccines as the cure for everything. There is a certain type of individual who is an excellent student and absorbs all the knowledge that his textbooks and teachers can impart up to the moment he obtains his medical degree, but who from henceforth depends entirely on the advertising columns of the medical papers and the catalogues of the manufacturers of pharmaceutical substances for his subsequent education. In the hands of this individual it is not surprising that vaccines are unsuccessful. The fault does not lie with the vaccines, but with the practitioner. When Jenner wrote to William Hunter telling him his theories regarding the possibilities of vaccination, the latter replied, "Don't think, try; be patient, be accurate." Only too many practitioners take the first half of this advice. They don't *think*, "Is there any other cheaper, equally efficacious remedy," but they just *try* a staphylococcal vaccine on a patient suffering from impetigo, when a better result could be obtained by the application of unguentum hydrargyrum ammoniatum dilutum. When they have a chronic sinus to deal with which previous surgical treatment has failed to cure, they don't *think*, but send to the bacteriologist for an autogenous vaccine and possibly close up the opening of the sinus, turning it into an abscess cavity, instead of combining surgical treatment with the vaccine therapy and thereby producing a permanent cure.

The object of giving a vaccine is to give a stimulus to antibody production, and is particularly suited to chronic infections where the infection is not sufficiently acute to produce the requisite antibody response. In acute infections the body has already more toxins than it can deal with and the addition of the vaccine can only have the same effect as does whipping a very tired horse; he may decide to give up the struggle altogether. In any case it takes a number of days to produce an immunizing effect and in the meanwhile the patient will either be better or dead; for such acute infections ready-made antibody in the form of anti-serum should be employed. Another point which is not fully realized is that for the vaccine to take effect the antibody must be able to reach the focus of infection; where this is not in direct contact with the body fluids, for example in the case of very superficial infections or abscess cavities, no results can be hoped for. In most infective processes there are more than one organism at work; the most easily isolated one is very frequently not the one that is the main cause of the trouble and a vaccine made from this organism will naturally give very disappointing results. Individual susceptibilities have to be considered; though natural immunity to disease is high in old age, little increase in immunity can be brought about by inoculation. Again most Indians are very susceptible to tuberculin, but to other vaccines they are hyposensitive. There are many conditions in which a stock vaccine is more valuable than an autogenous one, and by knowing this the

physician may save the patient considerable expense; but there are others in which an auto-genous vaccine is essential and in such cases money spent on stock vaccines will be wasted. Finally, vaccines are not likely to produce anything but temporary improvement if the original focus of infection is not eradicated or the portal of entry of the septic organism is not closed. For example, it is useless to attempt to treat a joint affection by means of a streptococcal vaccine if the ulcer in the intestine through which the organisms are entering is left untreated.

No physician would ever send a patient to the chemist with a request for "medicine" without stating the nature of the medicine and without instructions as to its application, yet nine out of ten physicians consider that they have done their duty completely when they send a patient to a bacteriologist simply with a request for a vaccine; the *thinking* has to be done by the bacteriologist, yet only too frequently his most explicit instructions are entirely ignored.

During the last twenty years much scientific work has been done on the subject of vaccine therapy; its value and limitations are appreciated by the bacteriologist and the specialist, but the future of vaccine therapy is dependent on the general practitioner's acceptance of it as a valuable weapon against disease worthy of serious study.

THE MADRAS EYE HOSPITAL AND THE INTERNATIONAL OPHTHALMOLOGICAL COUNCIL.

Our readers will join with us in congratulating Lieut.-Col. R. E. Wright, C.I.E., I.M.S., of Madras on his appointment to the International Ophthalmological Council. The position of the Madras Eye Hospital in world-ophthalmology is so prominent that it is only fitting that its Superintendent should be appointed to the Council. The following extract is taken from the *British Journal of Ophthalmology* for November 1929, p. 588:—

The International Ophthalmological Council have decided to hold the next Congress in Madrid in April 1933. Professor Lundsgaard (Denmark) is the new President of the Council, and Professor van der Hoeve (Holland) and Dr. Pflugger (Switzerland) are Vice-Presidents. Mr. Leslie Paton (Great Britain) is the Treasurer and Dr. E. Marx (Holland) the Secretary. It was decided that four of the eight members of the Council should retire and that they should be chosen by ballot. The lot fell to Professor Axenfeld, Dr. Byers, Professor Ovio and Professor Meller, and their places were taken by Professor Oguchi (Japan), Professor Roselli (Italy), Professor Wagenmann (Germany) and Lieut.-Col. Wright (India). Dr. de Schweinitz resigned and his place has been taken by Dr. Walter R. Parker to represent the United States. The remaining three members of the Council served on the old Council—Professor Coppez (Belgium), Dr. Marquez (Spain) and Dr. Morax (France).

BOMBAY MEDICAL COUNCIL.

The following summary of the proceedings of the meeting of the Bombay Medical Council held on the 2nd September, 1929, is published in the press for information.

1. The Council considered certain papers relative to the use by Mr. H. Ghose, a homœopathic practitioner,

of the following description after his name M.B.

and the use generally by (Homœopathic Physician)

homœopathic practitioners of medical titles which allopathic practitioners are entitled to affix to their names. Mr. Ghose having agreed to discontinue the use of the letters M.B. after his name, the Council resolved that a copy of the correspondence with Mr. Ghose be communicated to Government with an intimation that on the facts now elicited and having regard to the opinion of the solicitor no action under the Indian Medical Degrees Act appears to the Council to be necessary at present, but that taking into consideration the difference of opinion of the present solicitor to Government and of the former solicitor, and also the decisions of the Courts in previous cases, the Council consider that the opinion of the Advocate General should be obtained on the question.

2. The Council considered a representation from Mr. T. K. Phadke, M.B.B.S., and two others, practitioners of Panvel, complaining that under rule 2 of certain bye-laws framed by the Panvel Municipality under section 48 of the District Municipal Act, that Municipality has served them with notices for the payment of a "shop tax" on their dispensaries, such dispensaries being regarded as "shops," and resolved that the Government of Bombay be moved to exempt dispensaries kept by medical men from the operation of any bye-law as defined in rule 2 of the bye-laws of the Panvel Municipality.

3. The Council considered an application from Mr. John Michael Pereira, M.B., C.M. (Edin.), for the restoration of his name to the Bombay Medical Register whence it had been removed in 1926 under section 9 of the Bombay Medical Act, 1912, for unprofessional conduct in giving a medical certificate to a telegraphist without seeing him at the time of his illness, and resolved to accept the opinion of the Executive Committee that the name of Mr. Pereira may now be restored to the Register in view of a period of two years having elapsed since his name was removed and on account of his age.

4. The Council considered an application from Mr. Sobhagchand Vannali Shah for permission to be registered under section 7 (3) of the Bombay Medical Act and resolved to inform Government that as the applicant had not completed a course of training in any medical institution, the Council were of opinion that he should not be given the permission applied for.

5. The Council considered a letter from Government inviting the views of the Council on a proposal for the introduction of an Act for the registration of qualified dentists, together with certain other papers, including the draft of a Bill to give effect to the proposal, prepared by a Sub-Committee appointed by the Executive Committee, and resolved that the draft Bill as altered by the Executive Committee appears suitable; and that it should be submitted to Government with an expression of concurrence in the views of the Sub-Committee that until the Dental Board has had some practical experience of the working of the Act, the most economical arrangement would be to have the registration of dental practitioners undertaken by the same agency as the registration of medical practitioners, and that the incidence of cost generally should, in the beginning at any rate, be treated in the same way as is the expenditure connected with the Medical Council, i.e., by an annual grant from Government to meet such portion of the working expenses as may not be covered by the income derived from registration fees.

6. The Council considered certain papers received from Government relative to the recognition of the "M.D." of the American "A" Class Medical Institutions for the purposes of registration under the Bombay Medical Act, 1912, and resolved to inform Government that the Council were prepared to consider the applications of the American "A" Class Medical Institutions, provided those Institutions recognised the graduates of the Bombay University without the proviso of their degrees being subject to the recognition of the Examining Board in England.

7. The Council considered an application from Mr. J. M. Damany, M.B.B.S., F.R.F.P. & S. (Glasg.), for the registration as an additional qualification of the "D.L.O." (Lond.), which he had obtained, and resolved to inform him that it was not necessary to declare the diploma in question to be registrable in Bombay as an additional qualification.

8. The Council resolved to re-appoint Mr. Joseph Bocarro as Registrar for the year beginning on 1st November, 1929.

THE LONDON HOSPITAL FOR TROPICAL DISEASES.

We have been asked by the publishers of the *Gazette* to draw the special attention of our readers to the appeal on p. xcvi of the advertisement columns on behalf of the Hospital for Tropical Diseases, Endsleigh Gardens, London. Medical men in India are not wealthy, but there must be very many old students of the London School of Tropical Medicine with happy memories of this splendid hospital, which admits sufferers of every class and of all races who come for treatment from all parts of the tropics. Anyone who has visited or worked in the hospital must have appreciated how well it is run; since its first inception by Sir Patrick Manson thirty years ago, it has a splendid record of service.

The appeal is to raise the sum of £35,000, which is required for (i) additional "middle income" beds; (ii) a new pathological laboratory; (iii) a new clinical lecture theatre; and (iv) the endowment of beds for the care of necessitous patients. Contributions should be sent to Lieut.-Col. the Right Hon. Sir Leslie Orme Wilson, G.C.S.I., G.C.I.E., C.M.G., D.S.O., Honorary Treasurer, "Tropical Hospital Fund," c/o Messrs. Thacker, Spink & Co., Calcutta.

Some of our readers who are old students of the London School may be attending wealthy patients whose interest might be aroused in this connection, and their help asked for.

CALCUTTA SCHOOL OF TROPICAL MEDICINE AND HYGIENE.

EXAMINATION RESULT. L. T. M.

Session. July—September 1929.

Passed with distinction.

(Arranged in alphabetical order.)

1. Provat Kumar Kaviraj, L.C.P. & S. (Private Practitioner).
 2. Kalyan Singh Makhania, L.S.M.F. (Sub-Assistant Surgeon, Punjab Government).
 3. Mohd. Abdus Sami, M.B., B.S. (Sub-Assistant Surgeon, Punjab Government).
- Passed.*
- (Arranged in alphabetical order.)
4. Bilwa Mungal Adhicary, L.M.P. (Medical Officer, Lallachera Tea Estate).
 5. Kumudranjon Banerjee, L.M.F. (Local Indian Doctor under the District Board of Purnea).
 6. Subas Chandra Banerjee, B.Sc., L.M.F. (Kala-azar Doctor under Howrah District Board).
 7. Narendra Nath Barooah, L.M.P. (Subordinate Medical Officer, Kuliapani Tea Estate).
 8. Hans Raj Bhanmbi, L.M.P. (Sub-Assistant Surgeon, Punjab Government).
 9. Bhupendra Kumar Bhowmik, L.M.F. (Assistant Health Officer, Jalpaiguri District Board).
 10. Bhabani Prasad Chakravarty, L.M.P. (Sub-Assistant Surgeon, Government of Bihar and Orissa).
 11. Jamini Kumar Chakravarty, L.M.P. (Doctor, Helika Tea Estate, Upper Assam).
 12. Susil Kumar Chatterjee, L.M.F. (Private Practitioner).
 13. Kushal Singh Chaudhari, L.M.P. (Sub-Assistant Surgeon, Shahpura State).
 14. Lachhman Das, L.M.P. (Sub-Assistant Surgeon, Government of India).

15. Niranjan Das, L.M.P. (Sub-Assistant Surgeon, Gangpur State).
16. Ramanik Himatlal Desai, L.C.P.S. (Private Practitioner).
17. Henry Louis Francis, L.M.F. (Assistant Medical Officer, Bengal and North Western Railway at Barauni Junction).
18. Nalini Bandhu Ghosh Biswas, L.M.F. (Medical Officer, Serispore Tea Estate).
19. Kartar Singh Grewal, L.M.P. (Sub-Assistant Surgeon, Punjab Government).
20. Hem Chandra Guha, L.M.P. (In-Charge A. B. Railway Hospital, Haflong).
21. Chakrapany Ramchandra Iyengar, L.M.P., L.C.P.S. (Sub-Assistant Surgeon, Government of Madras).
22. Mohanlal Jareth, L.M.P. (Honorarily working in Balchand Hospital, Jhalrapatam City).
23. Codanda Bopanna Kariapa, L.M.P. (Sub-Assistant Surgeon under Coorg State).
24. Krishnaji Balwant Landge, M.B., B. & S. (Junior Assistant Surgeon, Railway Board).
25. Amarnath Marwah, L.M.P. (Sub-Assistant Surgeon, Punjab Government).
26. Priyanath Mukherjee, L.M.P. (Sub-Assistant Surgeon, Government of Bihar and Orissa).
27. Ramamurti Moni Patro, L.M.P. (Sub-Assistant Surgeon, Government of Madras).
28. Muhammed Abdul Rahmon, L.M.P. and College Diploma of Public Health, Madras (Medical Assistant, Health Department, Civil and Military States, Bangalore, Assistant Medical Officer).
29. Allada Sampson Anantha Rao (Sub-Assistant Surgeon, Government of C. P.).
30. Sudhindra Nath Raye, M.B., B.S. (Medical Practitioner).
31. Mir Mohd. Riaz, L.S.M.F. (Sub-Assistant Surgeon, Punjab Government).
32. Hira Lal Sachdeva, M.B., B.S. (Private Practitioner).
33. Kanapaka Satyanarayana, L.M.P. (Jail Sub-Assistant Surgeon, Jagdalpur, Bastor State).
34. Ayodhya Prasad Shukla, L.M.P. (Assistant Medical Officer, Government of C. P.).
35. Shivkumar Bhavanishanker Shuklya, L.C.P.S. (Honorary Worker, West Hospital, Rajkot).
36. Arumugam Theaga Ranjan, L.M.P. (Sub-Assistant Surgeon, Government of Madras).
37. Kangayam Subramania Thirumurthy, L.M.P. (Medical Practitioner, Chandragiri Taluq Board, Chittoor).
38. Pranlal Ranchhodlal Trivedi, L.C.P. & S. (Working as Sub-Assistant Surgeon on the Honorary Staff of the State Dispensary, Morvi, Kathiawar).
39. Trambaklal Hergovind Trivedi, L.M.P. (Sub-Medical Officer, Rajkot).

Current Topics.

Therapeutic Progress : Tuberculosis.

(Abstracted from *The Prescriber*, Vol. XXIII, July 1929, p. 242.)

HELIO THERAPY AND ACTINOTHERAPY.—Strandberg discusses the treatment of tuberculous conditions, particularly laryngeal, by means of heliotherapy and artificial light. The best source of light is unquestionably the sun, but the limitations attendant on the use of sunlight are many, and a substitute is generally necessary. The carbon arc most nearly approaches sunlight, and gives better and quicker results than the mercury vapour lamp. It is possible to effect a clinical cure in lupus vulgaris as well as in tuberculosis of the larynx by means of universal light treatment alone, but the period of treatment may be shortened considerably by the employment

of local treatment simultaneously with the universal treatment. In his Institute the carbon arc bath has been used on 435 patients with rhinolaryngological lupus vulgaris, and he has effected cures in 86.6 per cent. Of 41 cases of aural tuberculosis, 32 were cured. Of 203 patients with laryngeal tuberculosis, 113 were cured. Patients with intrinsic involvement do better than those with extrinsic tuberculosis. Of those who suffered from hoarseness or aphonia the voice became clear in 90 out of 110 cases.

Laird reports the study of 220 cases of uncomplicated pulmonary tuberculosis, of which 110 received sun treatment and 110 merely hygienic and rest treatment during the same period. He concludes that heliotherapy, while not essential to recovery, is distinctly advantageous in patients with comparatively few symptoms or manifesting only slight activity and showing a tendency to fibrosis. In the more active cases of pulmonary tuberculosis so little is to be gained by it as compared with rest and fresh air that one should use discrimination in prescribing it. Its results are not spectacular, and its omission is not detrimental to the patient's interests.

Actinotherapy ("artificial heliotherapy") has been tried for several years in the Edinburgh City Hospital by Mekie, who reports somewhat disappointing results. Since 1924 all cases of surgical tuberculosis in which there was no definite contra-indication, such as pulmonary lesions or intolerance to light, have had routine treatment with a carbon arc lamp. No deleterious effects were observed, though some patients were found to be more tolerant to treatment by the mercury vapour lamp. While in many cases the clinical results were gratifying, the statistics show that cases of spinal and abdominal disease did well, those of hip disease were less satisfactory, and those of disease of the knee-joint and of the cervical glands showed no improvement. The average duration of stay in hospital was materially increased in all cases. Mekie concludes that actinotherapy, as a treatment for surgical tuberculosis, has been overrated, and that it does not change the fundamental principles of treatment of that disease. It is merely a useful aid to treatment, as are many drugs.

GOLD COMPOUNDS.—In a recent issue of *The Prescriber*, Dyson discussed the chemotherapeutic compounds of gold. These he classified in several groups: the cyanide group, which includes *Aurocyanan*; the aurothio group, including *Krysolgan*, *Solganal*, *Triphal*, *Lopion*, and *Allochrysine*; and the double thiosulphate of gold and sodium, known as *Sanocrysin*. After a description of the chemical and therapeutic properties of these compounds, it was shown that the whole question of gold therapy is complicated by two important factors. In the first place, the activity of gold compounds is greatly reduced in the presence of serum, the reduction factor being about one-thirtieth. Secondly, the peculiar nature of the infection against which the activity of these compounds is mainly directed—the tubercle bacillus—makes the use of any therapeutic agent one of great difficulty. Chemotherapy has always been faced with the problem of getting the active preparation to the spot where its activity is required, and in no other disease is this problem more acute.

Sanocrysin.—Reporting on the treatment of pulmonary tuberculosis by sanocrysin, Burrell (London) remarks that the most notable change is the diminution in the quantity of sputum and the disappearance of tubercle bacilli from the sputum; the chief indication, therefore, for the use of sanocrysin is when the sputum continues and contains tubercle bacilli. Another type of case in which this drug is useful is when collapse has been induced in one lung by artificial pneumothorax and the disease begins to spread to the other side; in such cases it is sometimes possible to check this development and thus to secure maintenance of the pneumothorax. In acute pulmonary tuberculosis sanocrysin has not proved of much value, but combined with pneumothorax it offers the patient a good chance. Collapse is induced in the worse lung, and sanocrysin is used to check the spread of the disease in the other lung. Burrell gives it by intravenous injection, starting with 0.1 gm.; if no reaction supervenes he gives 0.25 gm. three days later,

then at weekly intervals 0.5, 0.75, and 1.0 gm. If a reaction occurs after any dose, the dose is repeated after the reaction has subsided, or a smaller dose is given if the reaction has been severe. Complications noted in some cases were: albuminuria in about 50 per cent., but transient and mild; metallic taste in the mouth occasionally; vomiting in 20 per cent. but not serious; rheumatic pains in a few cases, severe in one case; slight febrile reaction in about 30 per cent.; erythematous rash in a few cases, in some cases severe; painful arm caused by injection outside a vein, relieved by sodium thio-sulphate. In the early days serum was given before sanocrysin to ward off complications, but Burrell has never found it of any value.

Stobie and Hunter report on its use in forty-five cases during the past two years. Sanocrysin, they conclude, cannot be regarded as a specific in the treatment of pulmonary tuberculosis, though in suitable cases it shortens the period of routine treatment, and there is greater possibility of the improvement following institutional treatment being maintained. In carefully selected cases it is of value as an adjuvant to other methods of treatment. In bilateral disease it will help to clear the better lung and allow the establishment of artificial pneumothorax in the other. Used with care it is of value in the treatment of the acute exacerbations in chronic fibroid disease. By ridding the sputum of bacilli even for a short time it must limit the spread of the disease.

Heaf now records results in 97 cases of pulmonary tuberculosis. He concludes that, provided the patient has fairly good physique and no abdominal tuberculosis, and that other vital organs are normal, results with sanocrysin may be expected to be good. It is particularly useful in bilateral cases treated by collapse therapy. By suitable dosage all shock and unfavourable symptoms can be avoided, and the patient's weight should increase throughout treatment. The remote results are encouraging only in those cases which lose their tubercle bacilli and become clinically arrested after treatment. Sanocrysin is well tolerated by children, and has given encouraging immediate results in children suffering from pulmonary tuberculosis who did not respond to routine treatment.

Clarke and Haddick report a control observation on 97 patients, 57 of whom received sanocrysin treatment, the remaining 40 serving as controls. The results are given in considerable detail, and the general conclusion is that those treated with sanocrysin did better than those not receiving this treatment.

Several reports from France are worthy of notice. Farjon, Maizilly, and Lefevre think that untoward effects, when these occur, are the result of excessive dosage. In small doses sanocrysin is undoubtedly beneficial; the general health improves, cough diminishes and bacilli disappear from the sputum, weight increases, and fever progressively lessens. Improvement, however slight, often raises the patient's morale—an important factor in treatment. The doses given weekly by intravenous injection are: 0.05, 0.1, 0.15, 0.2, and 0.25 gm. this last dose being repeated until about 2.0 gm. has been administered. To avoid cumulative action, 40 to 60 days should elapse between the courses. Sanocrysin is of no benefit in acute tuberculosis, but only in the chronic febrile or subfebrile types. It is contra-indicated in cases with renal or digestive complications, in cases of advanced cachexia with hectic temperature, and tuberculous laryngitis.

Bernard and Mayer have administered sanocrysin treatment to 142 patients suffering from pulmonary tuberculosis. They do not regard it as a specific remedy for that disease, but they affirm that it has a definite therapeutic action. They do not credit it with bactericidal action: its effect is exercised on the lesion, at least in the lung.

A report by the Sanocrysin Research Committee of Japan is by no means encouraging. The most the report can say in favour of sanocrysin is that it is a stimulant in the stationary proliferative type of pulmonary tuberculosis. It was found that it caused but little

structural alteration in the tubercle bacilli, and did not deprive them of their acid-fast properties. Its germicidal action was extremely low, and no evidence was obtained that it had any lytic action on the bacilli. Therapeutic experiments with animals gave entirely negative results, and tests on tuberculous patients were equally disappointing. The general conclusion is that sanocrysin is not a specific agent in the cure of tuberculosis: that it does not directly destroy the bacillus; that it may be useful on occasion for stimulating cases of a stationary type which do not respond to the usual sanatorium treatment. On the other hand, it is an intensely toxic substance, and unless used with great care it may cause serious damage to the patient's tissues.

Two cases have recently been reported in which sanocrysin, under the influence of sunlight, caused pigmentation of the skin. Beaumont describes a lilac-coloured pigmentation of parts exposed to the sun in a patient who had been receiving sanocrysin. Savy reports a very similar case. This was successfully treated with sodium thiosulphate, at first 6 grains intravenously, and later 15 grains orally thrice daily being given, with local application of Lassar's paste.

Vaccine Treatment.—Raw reports further on the attenuated vaccine introduced by him some years ago. With the object of preventing tuberculosis in dairy cows and thereby reducing the surgical tuberculosis in children caused by infected milk, Raw has for the past five years immunized calves shortly after birth by giving them injections of vaccine from human bacilli. The results have been excellent, the immunity lasting for two years or even longer. Raw attributes the unfavourable results from tuberculin treatment to the use of virulent cultures of human bacilli. The disturbing reactions caused by such cultures are entirely obviated by the use of attenuated bovine cultures. In early infections his attenuated vaccine seems to give sufficient active immunity to enable the tissues to produce antibody to deal with the infection, and, what is of greater importance, to limit the spread of the disease in the organ affected. Raw says that a case of pulmonary tuberculosis should be treated by a vaccine prepared from bovine bacilli, and a case of surgical tuberculosis by a vaccine prepared from human bacilli. The dosage should be carefully graduated, and a course of treatment should consist of twelve weekly injections, the maximum dose being 0.01 mg. In no case are any reactions produced.

Jenkins* having used Raw's attenuated vaccine, and subsequently various fractions of this and of a virulent strain, realized that such precautions were unnecessary since the method of detoxication used for residual vaccine rendered the virulent strain safe. As at first prepared, his residual antigen was liable to cause abscesses at the site of inoculation. He has now elaborated two antigens—No. 3, the principal, and No. 1, the auxiliary—which are free from this defect. No. 3 is composed of human and bovine strains of *B. tuberculosis* by a process described in detail. No. 1 is an auxiliary to the main antigen and is used only in a certain type of case. It is simply a saline extract of the human type of Raw's attenuated strain, and its preparation is described also. The immediate clinical results are described as satisfactory, approximately two-thirds of all cases of pulmonary tuberculosis obtaining appreciable benefit, though the duration of the improvement is at present unknown. The original paper should be consulted for details of preparation and methods of administration.

Allergin.—Jousset calls attention to a preparation *l'allergin*, extracted by a special process from the tubercle bacillus. It differs in some respects from tuberculin, the chief difference being that it has an antigenic therapeutic effect, while tuberculin is credited with having only diagnostic properties. Jousset used allergin treatment in all kinds of chronic tuberculosis, with or without fever, if the patient was not cachectic. More or

less pronounced immediate, general, focal, and local reactions follow subcutaneous administration of allergin, after which is observed a transient amelioration of all functional symptoms and an improvement of the general condition; the physical signs of the tuberculous lesions, however, are not much improved. The amelioration may be maintained by one or two subcutaneous administration of allergin a month. Jousset explains the good effect of the treatment not only by the immunizing properties of the allergin itself, but also by the auto-immunization of the patients in response to the focal reactions.

Crystalline Tuberculin.—Seibert claim that the active principle of tuberculin is protein in character. Mention was made of the production by Seibert of this protein in crystalline form. Recently Seibert has published a full account of the investigations leading to this discovery. Evidence is presented to show that a water-soluble protein of the nature of an albumin has been obtained from tuberculin in crystalline form, and that this crystalline protein has been recrystallized as many as fourteen times without loss in its specific biological activity—a fact which leaves little doubt that the active principle of tuberculin is a protein. This crystalline tuberculin is extremely potent, but is unstable and easily becomes denatured, which explains the very small yield of crystals obtained. Seibert suggests that, if the specific toxic factor in tuberculin is a protein, the tuberculin reaction must be an allergic protein reaction.

B. C. G. Vaccine.—The work of Calmette, of the Pasteur Institute, Paris, directed towards the protection of infants and young children by means of "B. C. G." or *Bacille-Calmette-Guerin*, a living culture of highly attenuated bacilli, has recently been the subject of much writing. Calmette himself has issued a further report, bringing his results to September 1928. The mortality among the vaccinated infants has been only 2.3 per cent., while that among the non-vaccinated was as high as 18.5 per cent. Calmette thinks that with revaccination at the end of the first and third years, and possibly also at the ages of 7 and 15, a single injection of one-twentieth or even of one-fortieth of a milligram of "B. C. G." should confer permanent immunity. In France alone nearly 100,000 children have been vaccinated with "B. C. G."

Unfortunately Calmette's enthusiasm was not shared by all of his colleagues, some of whom attempted to discredit the method. A rather heated controversy resulted, from which Calmette appears to have emerged triumphant. The subject has been investigated by the Section of Hygiene of the League of Nations, whose report is presented by Bernard. The result of this investigation is to show that "B. C. G." is unlikely to produce tuberculous lesions (one of the accusations made against it), and that it confers a certain degree of immunity. The conference, however, suggested that the League of Nations should engage expert statisticians to go into the question of collecting and analysing the mortality and morbidity tables of infants vaccinated and unvaccinated.

Meanwhile many reports, both favourable and the reverse, have appeared in medical literature. According to Poix the Pasteur Institute has, during the past seven years, sent out more than 300,000 doses of "B. C. G." vaccine. Not a single accident has been reported; even disturbances in digestion or in growth have not been observed. A slight micropolyadenitis has occasionally been noted, but this has always disappeared in a few weeks and has had no effect on the general condition of the infant. A study of the records of over 3,000 vaccinated infants under one year of age and living in a tuberculous environment shows a general mortality of 3.1 per cent., whereas the mortality for unvaccinated infants, regardless of environment, is 8.5 per cent. For infants aged from 1 to 3½ years and exposed to familial contagion the tuberculosis mortality among the vaccinated is only 0.2 per cent., whereas among the unvaccinated of the same age it is seven times as great. As yet it is impossible to state with certainty the duration of the immunity conferred by "B. C. G." vaccine. Poix thinks that all new-born infants should be vaccinated. The

*Jenkins, C. E. The treatment of pulmonary tuberculosis with a residual antigen: method of preparation and clinical results obtained: *British Journ. Tuberc.*, 1928, July, pp. 126–136.

subcutaneous route, however, should be reserved for specially organized clinics, and only the oral route should be used by the general practitioner. This limits the use of "B. C. G." vaccine to the first ten days of extra-uterine life, because it has been shown that the digestive mucosa is permeable for bacilli only during the first few days of life.

Leuret and Caussimon review Calmette's work and criticize his conclusions that "B. C. G." vaccine is entirely innocuous and completely efficacious. A new strain of the tubercle bacillus of extremely low virulence has been evolved, but experimental evidence by no means proves that these bacilli are incapable of giving rise in ultra-susceptible subjects to tuberculosis. Further, it is too soon to state positively that the vaccination is absolutely preventive against tuberculosis. A small number of vaccinated infants have died of the disease; and Calmette himself admits that it is not immunity which is conferred by vaccination, but only a greatly increased resistance to tuberculosis. They contend that not until the present vaccinated infants have passed safely through the critical stage of puberty to adult life can final proof of the value of "B. C. G." be forthcoming. Meanwhile they doubt the wisdom of vaccinating infants who are not exposed to infection, though strongly recommending it in those whose environment would render contagion inevitable.

Weill-Halle and Turpin have made 613 peroral and 23 subcutaneous vaccinations with "B. C. G." and conclude that it is harmless. During the first ten days of life it can be given perorally, three doses being given according to Calmette's prescription; this should be repeated when the child is one year old and again when it is three years old. After the first ten days of life the vaccine may be given subcutaneously if two negative cutaneous reactions have been obtained at 8-day intervals. The dose subcutaneously is from 0.01 mg. to 0.5 mg. The vaccinated infants should be isolated to preclude the possibility of infection during the period of immunization.

Troisier and co-workers, as the result of certain experiments with old men, and because tuberculosis has been observed in persons of over 60 years, advocate preventive vaccination with "B. C. G." in all adults and even in old persons.

Calmette's statistical methods are criticized at some length by Greenwood, who shows that the figures given by Calmette are fallacious or misleading. The percentages, he says, are based on totals too small to give an accurate estimate, and in some cases they are not even correct. The positive evidence of a statistical character as supplied by Calmette is ambiguous.

Wallgren advocates intradermal vaccination as against the peroral method. He does not consider a child properly vaccinated unless it becomes tuberculin sensitive after inoculation. He has done some comparative experiments on the vaccination of new-born children, partly with peroral administration, using the French doses of, in all, 30 mg., and partly with the intradermal inoculation of 0.1 mg. Those treated intradermally were tuberculin sensitive after some weeks, while those inoculated perorally quite failed to show such sensitiveness. It will be a long time, however, before one can amass in intradermally vaccinated children statistics such as those given by Calmette. Wallgren can only say that so far no child vaccinated by his method has developed any tuberculous disease after exposure in its home.

Petroff and colleagues are doubtful about the ultimate harmlessness of "B. C. G." vaccine. The "B. C. G." organism in its undissociated form is only slightly virulent for guinea-pigs and rabbits. Its virulence can doubtless be kept at a low level by cultivation on laboratory medium, but the human body is different from laboratory medium. It is impossible to predict what changes may occur in course of time if "B. C. G." is implanted in the human body and is accidentally carried from one human being to another. There are indications that an avirulent micro-organism may be transmuted into a virulent form by cultivation on a medium containing its antiserum. Petroff and his co-workers believe, therefore, that the

use of "B. C. G." in prophylactic immunization may be a dangerous procedure.

Experiments with "B. C. G." vaccine as performed by the Ukrainian Commission are reported by Tzekhnovitzer. The conclusions arrived at by the commission are as follows:—(1) Calmette-Guerin bacilli injected in small or large doses into healthy or weakened guinea-pigs produce only localized lesions with a retrogressive tendency; even successive passages from one animal to another never result in progressive tuberculous processes; (2) Calmette-Guerin bacilli introduced into guinea-pigs which are thereafter subjected to repeated injections of tuberculin do not increase in virulence; (3) cultures of "B. C. G." isolated after one or two passages in the guinea-pig were not virulent; (4) the tissue culture method permits demonstration of the non-virulence of "B. C. G."; (5) the vaccination of laboratory rodents with "B. C. G." gives relatively good results; (6) the vaccination of cattle with "B. C. G." confers a definite resistance to experimental intravenous injection of virulent tubercle bacilli; (7) the "B. C. G." eliminated in the milk of cows is completely avirulent; (8) studies made over a period of more than two years prove that the use of "B. C. G." for the preventive vaccination of new-born infants is harmless. The very low mortality from tuberculosis observed in vaccinated infants in an infected area is in favour of vaccination by Calmette-Guerin's method.

Heynsius van den Bergh vaccinated ninety infants according to Calmette's method, keeping them from the source of infection for 10 to 12 days. (Calmette prescribes a month). Careful examination showed the children to be free from tuberculosis before exposure. One child died of congenital syphilis at the age of two months; enlarged mesenteric glands containing tubercle bacilli were found, but no tuberculous changes could be detected in these glands. The method appears therefore to be harmless. Twenty cases were observed for at least eighteen months, and fifty control cases were used for comparison. One death took place among the vaccinated children; nine among the controls. The remainder of the vaccinated children appear clinically free from tuberculosis, but x-ray examination reveals signs of the disease in the lungs of a few, although the disease appears to be benign.

Chiari, Nobel, and Sole find that intraperitoneal treatment of guinea-pigs with "B. C. G." does not protect them from subsequent infection, although in some instances life apparently is prolonged. They regard the efficacy of immunization with "B. C. G." vaccine as very questionable.

Kraus finds from experiments on guinea-pigs and rabbits that "B. C. G." possesses a certain virulence, but that the processes which in excites tend to remain localized and the lesions to disappear completely. He thinks that it is too early to give out the vaccine for general use in human beings.

Munoyerro records his observations on 757 infants at the Foundling Hospital at Madrid who had been inoculated with "B. C. G." vaccine. The general mortality was 28.5 per cent., as compared with 35 per cent. among 1,174 infants who did not receive the vaccine, and the mortality from tuberculosis 2.24 per cent., as compared with 4.25 per cent. among the controls. Munoyerro concludes that, in view of the smaller number of cases of tuberculosis found among the vaccinated, the "B. C. G." vaccine is not dangerous. It does not invariably protect against tuberculosis, though possibly in the vaccinated cases in which tuberculosis was found the infection was of intra-uterine origin, or so massive an amount that vaccination had no power to control it. He thinks that before the employment of "B. C. G." is generalized or its use made compulsory it should be restricted to maternity hospitals and orphanages, or to patients living in an infected environment, from which the vaccinated subject should be immediately removed.

Artificial Pneumothorax.—The employment of artificial pneumothorax in the treatment of pulmonary tuberculosis has been a recognized method for about quarter of a century, its effects being particularly good in cases where

the disease is limited to one lung and the pleura is free. Good results have been effected also in bilateral cases with the aid of sanocrysin, collapse being produced in the worse lung while sanocrysin is used to check the spread of the disease in the other lung. This method has already been described in the section dealing with sanocrysin.

A statistical study of the efficacy of artificial pneumothorax has recently been presented by Rist and Hirschberg. The after-history of patients so treated at the Laennec Hospital is compared with that of others who did not submit to the treatment, being unwilling or unable to do so. The classes are not strictly comparable, but the results offer a fair comparison. The patients selected numbered 759, and were suffering from unilateral disease, tubercle bacilli being constantly present in the sputum; the controls numbered 463. At the end of the period under review (1912 to 1926) 52 per cent. of the treated patients were clinically healed, being free from symptoms, showing no tubercle bacilli in the expectoration, and being able to lead a more or less normal life; 32 per cent. were dead, and the remainder either unimproved or worse. Approximately 54 per cent. of the controls had died, and none of the remainder was fit for employment or had ceased to be infectious. If the number of patients showing signs of progressive disease be added to the deaths, the percentage for treated cases is 44 and for untreated 82. A further study of patients treated and untreated between 1919 and 1921, and since observed for seven years, shows 90 per cent. of deaths among controls and little over 40 per cent. among treated patients, while of the treated patients 35.8 per cent. were classed as healed. Nearly half of the deaths among treated cases occurred in the first two years following induction. It is noticeable that the mortality among females greatly exceeded that among males; this is attributed to an inferior power of resistance. Rist and Hirschberg find that after the fifth year the danger of relapse is not great.

The Radiational Treatment of Corneal Ulcers.

By W. S. DUKE-ELDER, M.A., D.Sc., Ph.D., M.D., F.R.C.S.
(*The Brit. Med. Journ.*, July 13th, 1929, p. 41.)

In a previous paper in this *Journal* a preliminary account was given of the application of ultra-violet light to ophthalmological diseases. Subsequent experience, extending to well over a thousand cases, has wholly confirmed the opinion then tentatively put forward; but the results of radiational treatment applied locally to ulcerative conditions of the cornea merit a separate and more detailed account.

The action of ultra-violet light is primarily abiotic—that is, destructive. The most obvious effect produced in the radiation of a cell is the photochemical denaturation and subsequent coagulation of its proteins. This, with other reactions, involves the production of a certain amount of trauma, which may lead to the partial or complete destruction of the cell, an effect which is now well recognized in the desquamation of the outermost layers of the skin after radiation. In the tissues of the eye a precisely similar reaction takes place; with small intensities of radiation the cells are injured, with great intensities they are destroyed. It is this end, under proper control, which is desired in the treatment of ulcers of the cornea, and the active response which the traumatism of light evokes repairs, and more than repairs, the damage which is done.

Histological studies carried out on the cornea of rabbits which were subjected to radiation with ultra-violet light in doses considerably above those which may be used clinically, show no observable change after radiation until four hours have elapsed, when, in both the superficial and basal cells of the epithelium, some spacing out and oedema are evident. The nuclei of some of the more superficial cells then show the presence of acidophil

granules, which take on a sharply defined eosin stain. After six hours these same changes are much more generally evident, and the arrangement of the superficial layers becomes somewhat irregular. The pathological changes are most striking after twelve hours. A large number of the nuclei of the epithelial cells take on the red stain markedly; some remain granular, in others the granules appear to have coalesced to form amorphous red "inclusion bodies," and a nucleus may contain a very large number of the former or be entirely converted into one or two of the latter. At a later stage these inclusions tend to bulge out the nuclear membrane, giving the nucleus a polymorphic shape, and finally they may be extruded altogether into the cytoplasm. Thereafter, if the cell is a superficial one, it appears to be cast off. At any stage before this the process may stop and the cell return to normal in appearance and staining reaction. From twelve to twenty-four hours after radiation desquamation is proceeding in the central area, around which there is frequently, but not invariably, a heaped-up region of proliferating epithelium. Meanwhile the substantia propria shows somewhat similar changes, which gradually decrease in intensity in the deeper layers, and from the limbus an infiltration spreads, composed very largely of eosinophils, although some polymorphonuclear cells are present. After thirty-six hours this limbal infiltration becomes more marked, blood spaces of considerable size are seen, and the eosinophils, which preponderated initially, are largely replaced by a massive invasion of polymorphs.

About fifty hours after radiation the epithelium near the periphery becomes more regularly arranged, and over the desquamated area a single layer of cells, the nuclei of which show no acidophil properties, begins to appear. The process of regeneration goes on with surprising rapidity and little evidence of cellular activity until, at seventy-six hours, the epithelium is two or three layers thick. At the limbus vascular infiltration is at its height; large new blood spaces, frequently surrounded by young fibroblasts, are present in great numbers, while the whole tissue in this region, and for some considerable distance into the cornea, is infiltrated with blood cells. This marked vascular reaction at the limbus seems to be a secondary feature, and is not evident histologically until the abiotic changes are well advanced; it is probably stimulated by the absorption of the products of protein disintegration. In seven days the cornea is again entirely normal.

Therapeutic Effects.

It is probable that the therapeutic effect of ultra-violet light when applied to the cornea in inflammatory, ulcerative, and degenerative conditions depends on the following factors. In the first place, pathogenic micro-organisms in the most superficial layers of this tissue will be directly killed. The lethal action of short-waved light upon such organisms is well known, and in a transparent tissue like the cornea this bactericidal power will be much more effective and extend more deeply than in an opaque and highly absorbent tissue like the skin. Where there is much inflammatory reaction and infiltration present in the superficial corneal layers, however, the greater part of the abiotically active rays will be absorbed, and in this case any lethal effect will necessarily be slight and practically restricted to the surface; but in proportion as some degree of transparency remains, bactericidal action will be greater and extend more deeply. In the second place, the superficial cells of the diseased corneal epithelium are killed and cast off with contained bacteria. Thirdly, the intense vascular reaction at the limbus and the invasion of the cornea by blood cells and inflammatory oedema will flood the diseased area with bactericidal influences. Fourthly, the stimulation to rapid and healthy regeneration of the exfoliated epithelium is a beneficial factor in any type of ulcer, but one which becomes of first importance in chronic and recurring conditions. Finally, it is probable that the absorption of the products of disintegration of the proteins of the cells will exert a favourable influence over the local immunological mechanism.

The Biological Action of Ultra-violet Light upon the Lens.

We have seen that the traumatization with the subsequent active response which ultra-violet light rays evoke, when used in clinical doses, is the action which is desired in the cornea. In the lens, however, the case is different. This is an avascular tissue in which active repair is comparatively lacking, and consequently any damage which may be done to it tends to be cumulative. Coagulation of the proteins of its cells is recognized clinically as cataract, a condition which has been produced experimentally by radiation with ultra-violet light. With radiation of such intensity as does not produce an opacity, changes take place in the colloid system of this tissue which result in the proteins becoming more labile and their subsequent coagulation by other influences more easy. Moreover, the autoxidation system of the lens, upon which it probably depends in large measure for the maintenance and regulation of its metabolism, is damaged by ultra-violet light; while, in addition, the permeability of the capsule is altered, thus further increasing the susceptibility to pathological changes. It has been urged that, in the comparatively small doses in which ultra-violet light is used clinically upon the eye, there is little fear of causing permanent damage to the lens; but it is to be remembered that small doses, such as have no apparent effect, produce physico-chemical changes which predispose to the formation of cataract. In addition, in many diseased eyes the possibility of a complicated cataract without any artificial stimulus is by no means remote. In any technique of local phototherapy, therefore, it is essential that the lens be excluded from the path of the incident rays.

Clinical Technique.

In the treatment of corneal ulcers by ultra-violet light the first essential is that the beam should be adequately controlled so that it may be limited to the diseased area; in this way unnecessary traumatism to the healthy parts of the cornea is avoided, and the lens is excluded altogether from the path of the rays. For this purpose I have introduced an "ophthalmic radiation lamp," which has been already described in detail elsewhere. In principle it is a modified Gullstrand slit-lamp fitted with a mercury vapour lamp instead of the usual nitra lamp, and provided with an optical system of quartz, mounted on a freely movable arm. The last lens in this system is capable of accurate focusing and fine adjustment in two planes by means of an Arruga screw arrangement, and the precise incidence of the beam is controlled by observation through a Zeiss binocular corneal microscope. Interposed in the beam is an adjustable diaphragm and a system of filters, by means of which the nature of the light employed can be varied. For therapeutic purposes the ultra-violet light is employed unfiltered, but a screen which cuts off the abiotically active rays (such as uvioi glass or Crookes's B) is useful for examinations for diagnostic purposes; with these all the advantages of a slit-lamp with red-free light are attained. With such an instrument a beam of considerable intensity and any desired size can be used, its incidence can be adequately observed and controlled, and in all cases, it is easy to avoid the lens by inclining the beam at a sufficient angle. The most convenient procedure to adopt is to instil cocaine into the eye, which is followed by fluorescein, which is again washed out by cocaine. The patient is then set down to the radiation lamp, and, a uvioi filter being interposed in the beam of light, the nature and extent of the ulcerative process are examined through the microscope. A remarkably beautiful and well-pronounced fluorescent effect is produced in this way, and the depth and extent of the disease are clearly delimited. The beam is adjusted so that it plays upon the ulcerated area, and no other region of the cornea, and the uvioi filter is thereupon turned off and the unfiltered light allowed to play upon the eye. If the patient is unable to keep his eye open during the whole time of the treatment there is no disadvantage in interruptions, for intermittent exposures, within very wide limits, are additive in their

effects, and have the same accumulative action as a single long exposure.

Other methods have been proposed from time to time. Koeppé (1919) and Birch-Hirschfeld (1922) employ a carbon arc as the source of light, but this emits a very large amount of heat; infra-red rays readily penetrate into the tissues of the eye and are potent for harm, especially to the lens, while any attempt to filter them off necessarily reduces the intensity of the abiotic rays. Ascher (1922) uses a quartz rod as a director along which the ultra-violet rays are guided, but although such a method is very suitable for radiating the conjunctiva, it is impossible in this way, in the case of cornea, to control the beam of light with sufficient accuracy.

Dosage.

In radiating the cornea extreme care must be exercised with the dosage. I have found experimentally that the intensity of light required to produce a response is very slightly less than that required to produce an erythema upon the skin. It is to be noted that, as occurs in the skin, the response varies with different individuals; consequently the ideal method is to test the erythema dose on the skin of the arm of each individual patient, and to commence radiating the cornea with a dose slightly less than this. In many corneal ulcers, however, it may be inadvisable to wait the twenty-four hours necessary for the development of the cutaneous reaction, and in these cases it may be necessary to start treatment immediately with an average dose. This may be taken as representing a period of radiation lasting three to three and a half minutes with the apparatus described, where the mercury vapour lamp is of the atmospheric pressure (K.B.B.) type, and runs on 220 volts, 2 to 3 amperes. Once the initial dose is obtained and its reaction observed subsequent doses are based upon it, but any increases are to be graduated with care, for it must be remembered that a small increase will make the difference between a mild and a violent photophthalmia.

Since the beam is always kept at a focus upon the cornea, the distance of the lamp from the cornea is constant, and the dosage can be altered only by time. Allowance must be made, however, for the obliquity of the rays, for it is evident that if the rays are not falling normally upon the cornea their intensity per unit area will decrease with the degree of obliquity. Actually, the energy varies quantitatively as the cosine of the angle of incidence of the beam, this angle being that which the incident ray makes with the normal to the tangential plane. The following table gives the factor by which the time of exposure determined for a normal ray should be multiplied in order to give an equivalent exposure with oblique rays:—

Angle of incidence.	Cosine.	Factor.
0 (i.e., normal)	.. 1.000	× 0.00
15 degrees	.. 0.966	× 1.03
30 "	.. 0.866	× 1.16
40 "	.. 0.766	× 1.30
45 "	.. 0.707	× 1.40
60 "	.. 0.500	× 2.00

Some hours after the administration of a small exposure to a normal cornea there is a pricking sensation as of a foreign body in the eye, a sensation which is frequently accompanied by the appearance of haloes, and which is followed by the symptoms characteristic of photophthalmia. After intense doses the pricking sensation gives way to pain, accompanied by marked photophobia, lachrymation, and blepharospasm. The appearance of haloes is due to corneal oedema; the pain is due to the irritation of the corneal nerve endings after the trauma to the epithelium. It follows that in those conditions where the epithelium has already been destroyed (as in the majority of ulcers) pain does not occur, provided the rays have been allowed to play on the ulcerated area only. The latent period which elapses before the reaction starts is about eight hours. In practice, therefore, when dealing with cases when a subsequent reaction is expected, it is well to conduct the treatment during the afternoon so that the symptoms begin to assert themselves during the night. If the

patient has the eye bandaged up so that the lids do not abrade the radiated area, he frequently experiences no subjective symptoms at all, especially if a small dose of aspirin or bromide be given before going to bed to ensure sleep.

Clinical Indications.

Corneal ulcers of practically every kind respond well to radiation with ultra-violet light, but, inasmuch as the more simple types of ulceration tend to heal up with the usual methods of treatment, it is in the more severe, the chronic, and the recurrent forms that the beneficial effect of treatment can be seen to the best advantage. In the more simple forms healing without any opacity is usually obtained; and the method has been found extremely useful in cases of foreign bodies in which infection has already become evident. With the more severe types of ulceration radiational treatment is the method of choice. In hypopyon ulcers, for example, a greater chance of recovery is offered than can be expected from cauterization, with, at the same time, less permanent damage to the cornea. In a series of 190 cases of this type of ulcer published recently by Hoffmann at Königsberg the percentage of excisions of the eye was reduced to 4.6 from the percentage of 32 which obtained before radiational treatment was introduced. Chronic ulcers, also, associated with a varying degree of deep keratitis and corneal opacity, and sometimes with iridocyclitis, in which the eye has reached a torpid and sluggish state, and which have progressed over long periods in spite of the usual treatment, may frequently be made to heal over and remain quiet after a course of three, four, or more exposures to light. The deep lesions of acne may also be very favourably influenced.

There are, however, two conditions wherein the beneficial effects of treatment are very evident: recurrent ulcers, and phlyctenular ulcers. With regard to the former, especially those marginal lesions associated with a continually relapsing conjunctivitis, the ulcer itself readily clears, an end which is, of course, usually easily brought about. But after the epithelium round the ulcer has been desquamated in the photophthalmic reaction following exposure to ultra-violet light, the new layer seems so healthy and resistant that it is enabled to withstand the liability to break down on future occasions. As a general rule the ulcer heals up after the first or second exposure, and in the milder cases heals up, leaving a transparent facet; but it is preferable in most of these cases to give a third or fourth exposure, bringing about a mild reaction each time, involving a traumatism and renewal of the epithelium in order to render the possibility of recurrences more remote.

Acute phlyctenular ulcers occurring in children respond so well to general light treatment and efficient dieting and hygiene that it is not worth while, as a rule, to coax a child affected with this disease to submit to keeping its eye open in the beam of the slit-lamp. It is in the chronic cases which have gone on for years, leaving an ulcerated, opaque, and vascularized cornea, and involving continued irritation, frequently with acute exacerbations, that the method has its greatest use. Here again it is best employed along with general light baths. In these cases the eye quiets down and becomes white and comfortable, but the extensive opacities, which are already present with the resulting diminution of vision, remain.

One word may be said with regard to corneal opacities. In order to investigate claims in the literature, a series of nine cases of old corneal opacities were given a fair trial with local radiation. No results justifying the continuation of the treatment were seen anywhere. It is certainly the case, however, that recent opacities, such as those following ulceration, may be improved, and the prophylactic action of the treatment of ulceration by light in the prevention of opacity formation is very marked. Two factors seem to enter into this: the rapidity of healing with new-formed epithelial cells, and the large amount of vascularization which the photophthalmic response excites. To this extent its action would seem to be comparable to that of an irritant, such as dionine.

Coffee and Sterility.

(Abstracted from *The Medical Press*, September 25th, 1929, p. 249.)

SOME experiments made by Professor Stieve, of Halle, go to support the theory that female rabbits are more sensitive to caffeine than the males, and that caffeine has a toxic effect on the generative glands. In females dying from chronic caffeine poisoning, ovarian degeneration was observed, whereas in males the semen was no longer formed. The quantities of the drug which were used in these cases were much larger in relation to weight than are ever used in human therapy. Human beings, however, are much more sensitive than rabbits to caffeine, and a daily consumption of four or five large cups of strong coffee would be less than one-tenth of the poisonous dose for a rabbit. Professor Stieve is of opinion that regular consumption of strong coffee has a deleterious effect upon the generative capacity, and, indeed, that it may affect adversely the general health. In some measure to the inhibition of coffee he ascribes the sterility which has been observed among civilised communities. Mental strain is capable of diminishing the sexual impulse, and since mental workers are often accustomed to drink strong coffee, the cumulative effect may be productive of sterility.

Decompression of the Kidneys and the "Overflow" Bladder.

By FRANK KIDD, M.Ch.

(Abstracted from *The Brit. Journ. Urolgy.*, September, 1929, Vol. I, No. 3, p. 305.)

THE victims of enlarged prostate fall into three clinical groups, there is the man with increased frequency of micturition, diminished stream and consciousness of difficulty in passing water. There is the man who in addition develops occasional attacks of painful retention of urine. Finally, there is the man who suffers from an "overflow" bladder. Patients in the first two groups are seldom suffering from chronic uræmia, and for that reason their lives are not likely to be endangered by the casual passing of a catheter, provided sepsis is guarded against. Patients in the last group come under an entirely different category. Suffering from chronic uræmia, they live on the edge of the precipice of renal failure. Uninstructed or hasty catheterisation may be fatal.

The man with the "overflow" bladder is not particularly worried about himself because he has no pain or difficulty in passing water. All that he complains of is that he passes water every hour or so both night and day, and in consequence is suffering from lack of sleep. Sometimes he wets his bed. He has lost weight, has lost his appetite, is easily nauseated and may vomit. He is usually extremely thirsty. He looks thin and wasted, and is anæmic and slightly puffy about the eyelids. His skin is dry and inelastic, and there is loss of subcutaneous fat. Contrary to the usual teaching, he has a moist, clean tongue. His urine is clear and free from pus, of low specific gravity, and contains a trace of albumen and a few casts. Abdominal examination reveals a large clastic swelling protruding from the symphysis to the umbilicus, a painless atonic bladder. By means of rectal examination it is a difficult matter to estimate the exact size of the prostate, as the pelvis is crowded out by the large cystic bladder.

On no account whatever should a catheter be passed to empty such a bladder or to carry out functional tests on the urine. There is no pain to call for the immediate passage of a catheter, so that before steps are taken to decompress the bladder and kidneys gradually, the patient should be put to bed and the serious nature of his complaint be explained to him and his friends. If a catheter is passed and the bladder emptied suddenly, hæmaturia usually occurs and death ensues from uræmia. Hasty interference with a catheter carries with it a far higher mortality rate than any kind of operative interference.

With regard to renal-function tests, there is only one that is advisable and one that will prove the gravity of the renal back pressure. The blood urea should be estimated. In mild cases it lies between 50 and 100 mg. per 100 c.c. of blood, but it often exceeds 300 mg., and yet the patient can be steered through an operation and be restored to a healthy life if the principle of renal decompression be observed.

The presence of a giant "overflow" bladder means that there is temporary loss of tone of the bladder muscle, and hence no bladder pain. It means that some of the raised pressure of the urine in the bladder is thrown back on to the kidneys. The effect of this pressure on the kidneys is to cause an intermittent dull pain in the back of one or both loins. The patient usually states that he has no pain, but when questioned will admit that he has suffered for some time from "lumbago."

This back pressure on the renal pelvis is of a moderate degree, averaging about 15 mm., and seldom exceeding 30 mm. of mercury. As Hinman, Morrison and Lee Brown have shown from experiments on animals, the kidneys should be considered as a vascular sponge. Even the mildest rise of pressure in the pelvis of the kidney causes a stretching and narrowing of all the renal arteries and capillaries, with engorgement of the veins. Sudden release of this raised pressure allows blood to re-enter the arteries so rapidly that the capillaries burst and blood is extravasated into the substance of the kidney. The renal secreting tissues, already handicapped by ischemia caused by the back pressure, cannot withstand this further sudden strain and acute uræmia ensues. Clinically, if the bladder is emptied suddenly blood escapes from the ruptured capillaries into the renal tubules and hæmaturia is seen. If this hæmaturia is seen the patient seldom recovers.

A great surgical principle therefore emerges from these considerations. *In cases of overflow bladder the kidneys must be decompressed gradually.* One well-recognized method that has been in use for many years is to pass a catheter of small calibre fitted with a bung, the bung being in place before the catheter is inserted. The catheter is tied in position, measured amounts of urine are then drawn off every hour or every two hours by removing the bung. As these patients are usually making 100 ounces of urine in twenty-four hours, 5 ounces of urine should be withdrawn every hour, or 10 ounces every two hours. In this way the bladder will be emptied in the course of five days.

There are many objections to this procedure. Either too much urine may be drawn off at a time, or the bung may slip out and the bladder be emptied completely. Even if these dangers are avoided, urethritis, epididymitis, cystitis and pyelitis may occur and add to the dangers of an already dangerous situation. Finally hæmorrhage is likely to occur and the catheter become blocked by clots so that further emptying of the bladder may be rendered impossible.

Other methods that have been in use are to puncture the bladder by trocar and cannula, or to open the bladder, empty it completely and put in a tube. Both these methods transgress the principle of gradual decompression of the kidneys, and they should be condemned.

The writer's practice is to insert a "Malecot" rubber tube suprapubically into the bladder by a method he has devised, whereby not a drop of urine is lost while the tube is being inserted, and then to put the bladder on a balance immediately after the operation so as to decompress the kidneys slowly. The method has been made possible by devising a new type of instrument, namely, a tube knife.

A small incision is made rather high up above the pubes, the recti divided and the distended bladder exposed to the sight of the eye. The knife attached to the end of the obturator is made to pierce the tip of the tube. The tube is then stretched on to the obturator and the knife and tube plunged into the bladder at a point where no distended veins are seen. The catch of the obturator is thrown over by the thumb, the mushroom of the tube expands and the obturator is removed. The

tube is pinched between the thumb and first finger of the left hand and a large bung inserted into its mouth. It will now be found that the tube is in the bladder, that there is no leakage round the tube, and that not a drop of urine has escaped from the bladder. The wound is stitched up, dressings and a binder are applied, and the patient is returned to bed.

A table is placed at the side of the bed with some large hooks or an empty drawer on the top of the table, and a mackintosh on top of these. On the stand thus formed is placed a large slop-pail. A special "U"-shaped metal tube with an opening at the top of the "U" to prevent syphonage is attached to a piece of rubber tubing, at the end of which is a glass connection of such a size that it fits the "Malecot" tube. The bung is removed from the tube, the tube being pinched, and the glass connection is inserted into it. The metal "U"-shaped balance tube is now held up and caught over the edge of the slop-pail. The slop-pail is held at a height of about one and a half feet above the level of the patient's abdomen. At this height it will usually be found that no urine flows over into the slop-pail. The pail is gradually lowered until a little urine flows over into the pail. This gives the height of the pressure of the water in the bladder. The pail is raised some six inches higher than this and arranged on the stand by the side of the bed. A long piece of string is tied round the "U" tube and nailed to the wall as an additional security. It will now be found that during the next few hours every time the patient coughs or takes a deep breath a small amount of urine flows over into the pail. In this way the pressure of the urine in the bladder and kidneys is put on a balance without the need for any elaborate apparatus. The nurse is instructed on no account to lower the pail, as the patient's life depends upon keeping it at the proper height. In the course of three or four days the bladder gradually empties itself without hæmaturia, and after five days the pail and balance can be removed and the urine be allowed to drain away from the "Malecot" tube into a bottle suspended from the side of the bed in the ordinary manner. Whenever it is necessary to disturb the patient for purposes of nursing, the tube can be disconnected for a few minutes and blocked with a bung, and at the end of the manipulations the balance can be refixed without difficulty or danger.

This method is a distinct advance in the surgery of the bladder. It is the only simple method the writer has been able to devise by which it is possible to insert a suprapubic tube into the bladder without losing a drop of urine and to put the kidneys on a balance without any elaborate apparatus. He has carried out this operation on quite a number of patients with a blood urea of over 300 mg. per 100 c.c. of blood and they have done well. When the blood urea comes down to normal, indigo tests are carried out. When these prove satisfactory the prostate is removed at a second operation.

This is a method that can be widely practised, as only two special instruments are required. There is always time to put these patients to bed and carry out the operation without hurry and at a convenient time. They are not cases that have to be dealt with by passing a catheter in the consulting room as if it were a matter of life and death to empty the giant bladder. The patient having no pain can be persuaded to wait until proper arrangements have been made for gradual decompression of his bladder and kidneys.

Reviews.

STONE AND CALCULOUS DISEASE OF THE URINARY ORGANS.—By J. Swift Joly, M.D. (Dub.), F.R.C.S. (Eng.), 1929. London: William Heinemann (Medical Books) Ltd. Pp. 568 plus XVIII with 189 illustrations and four coloured plates. Price, 45s. net.

It is stated in the preface that no English book on stone has been published during the last twenty years.

An authoritative work dealing with this subject separately is certainly very welcome, especially in India where the disease is so common. As to the arrangement of the subject, the author states that this has been kept as simple as possible. "After a brief historical sketch and a chapter on the formation and general aetiology of stone, I have followed the anatomical order, separate chapters being devoted to stone in the kidney, ureter, bladder, etc. This classification is not perfect, but on the whole I feel it to be the most satisfactory."

Chapter I deals with the historical side of the subject. The history of stone dates back to the dawn of civilization. The earliest specimen of vesical calculus is said to be that described by Professor Elliot Smith, which is computed to be about 7,000 years old! The history of stone is described, as far as it is known, in ancient Egypt, India, Greece, Rome, the Dark Ages, during Arabic ascendancy, and so on up to modern times. It makes a story of the greatest interest to every surgeon. We learn that the suprapubic operation for stone was first performed by John Douglas in England about the year 1720, while it is described in the Ayurveda as being performed in India about the beginning of the Christian Era—that is to say, about 1,500 years earlier. Innumerable quack remedies were prescribed for dissolving stone. An early Hindu remedy included a mixture of butter, pepper and ginger, to which is added, drop by drop, the urine of a sheep. The famous Arab physician Avicenna "recommended laurel, cypress, the oil or ashes of scorpions, egg-shells, melon seeds, etc., for the purpose." The first lithotripsy instrument was introduced by Civiale in 1818, and numerous improvements followed designed by Heurteloup, Thompson, Bigelow, and Freyer. The first practical instrument for evacuating the fragments was invented by Clover in London, and Bigelow followed up the same idea, and introduced the modern evacuator, which made the operation of litholapaxy possible. In India, surgeons rapidly developed the operation, especially Keegan and Freyer, and the former first used small instruments suitable for children. The author observes that "there is no doubt that it is the operation of choice for uncomplicated vesical calculus," and this should be noted as there is a great tendency to-day to regard suprapubic lithotomy as a better operation. At St. Peter's Hospital from 1864—1873 the mortality after lithotripsy was 15.25 per cent., and the average stay in hospital about 100 days. In the decade 1915—1924 the mortality after litholapaxy was 2.2 per cent., and the average stay in hospital about 5 days.

The formation and composition of calculi are discussed in Chapter II. A calculus is defined as a "concretion formed of urinary crystals bound together by a colloid substance." A very full and interesting account of the biochemistry and incidence of stone in man and animals is given under the following headings: Part I—the composition and formation of calculi; Part II—the general characteristics of calculi; Part III—the aetiology of stone, general and personal.

Chapter III deals with renal calculus. A number of excellent illustrations of the condition are reproduced, and the aetiology, the characters of the stone itself, the pathology, symptoms, methods of examination—including over twenty pages on radiographic methods—diagnosis, course and termination, and treatment, are fully discussed in the space of 174 pages. This chapter contains a mass of information which it is not possible to go into in any detail, but one can state with confidence that there are few surgeons in active practice who will not add considerably to their knowledge of the subject by a perusal of its pages.

Urteric calculi are discussed in Chapter IV; these are stones which are permanently or temporarily impacted in the ureter. The great majority come down from the kidney and there is a history of renal pain, but a calculus may form in the ureter round a foreign body or above a stricture. It is a disease of middle life and is commoner in males. When aseptic the stone is composed of calcium oxalate, when infected it is phosphatic. The changes in the ureter and kidneys are described; the

symptoms caused by urteric stone; methods of examination; differential diagnosis; course and evolution; and treatment. Two important points are to be remembered, namely, that every urteric stone tends sooner or later to destroy kidney function; and, that medical treatment should be given up if the stone has not moved down to an appreciable extent in a month or six weeks, other treatment becoming necessary. If left unrelieved the further danger arises of the infection, if present, involving the other kidney.

The important subject of "calculous anuria" is discussed in Chapter V. This term is defined as "a sudden cessation of the excretion of urine, caused by the presence of one or more stones retained in the upper portions of the urinary tract." Four groups are considered; obstruction of both kidneys or ureters; obstruction of the only functioning kidney; obstruction of one kidney, its fellow being diseased; obstruction of one kidney, its fellow being apparently healthy. The state of the obstructed and of the opposite kidney, and the theory of reflex anuria are gone into; it is stated that probably all the phenomena of calculous anuria are explicable on the assumption that they are the result of changes in the blood and urinary pressures, without the necessity of considering any nervous mechanism. The signs and symptoms of this condition are considered as follows: prodromal symptoms, onset, clinical course, duration and termination. The mortality is very high, about 70 per cent., the patients dying between the 5th and 12th days. As regards examination and diagnosis, the most important points are the existence of anuria, its cause, and the kidney last obstructed. Treatment is either by catheterisation of the ureters, or by operative treatment; failing relief by catheterisation, drainage of the kidney becomes imperative. Late results depend upon two factors, the functional value of the kidney and the presence or absence of infection.

Chapter VI deals with vesical calculus, a subject of great interest to surgeons in India—the aetiology, characters of vesical stone, symptoms, methods of examination, differential diagnosis, and treatment. The enormous incidence of vesical stone in India and in some other tropical countries is ascribed to the frequency of stone in childhood; this is partly due to the poor quality of the food, and particularly to the deficiency of fat-soluble vitamin. An unhelped for improvement in this respect has followed the better feeding and hygiene of children in many parts of Europe. The largest vesical calculus referred to is one described by Pithas, which weighed 5 lb. 10 oz., and another by Randall weighing 4 lb. Over 90 pages are occupied in relating the story of stone in the bladder, and illustrated by photographs, radiograms, and very beautiful coloured drawings of cystoscopic appearances. As regards treatment, this is definitely surgical as no method has yet been discovered by which a stone can be dissolved *in situ*. It is definitely laid down that "every uncomplicated stone that is not too large to be grasped by the jaws of the lithotrite ought to be crushed." The indications and contra-indications are given. The author thinks that the type of lithotrite used by Freyer in India is the best on the market—Thompson's blades and a Bigelow handle. It will comfort those who have not had much experience of this operation to know that "injury to the bladder wall is a rare complication"; and this accident would never occur "if the surgeon would realize that the lithotrite should be kept steady in the middle line of the bladder, with its beak pointing upwards."

The last two chapters in the book, Chapters VII and VIII, deal with prostatic calculi and urethral calculi. Space forbids any further reference to these chapters. It will surprise some to know that a urethral stone may weigh as much as 24 lbs.

We venture to congratulate the author and the publishers on the production of this fine volume. It will be read with interest by every surgeon, as it provides an authoritative and up-to-date account of an important subject, and supplies at the end of each chapter a fully adequate list of references.

THE HISTORY AND TRADITIONS OF THE MOORFIELDS EYE HOSPITAL.—By E. T. Collins. London: H. K. Lewis and Co. Ltd. 1929. Pp. XII plus 226 with 27 plates. Price, 12s. 6d. net.

THIS is a most interesting book and deals with one hundred years' of ophthalmic discovery and development. Its primary aim is to put on record the traditions of the Moorfields' Eye Hospital for the benefit of past, present and future workers within its walls, but as so many giants in the art of ophthalmology have been attached to this institution the book will be of great interest to the world in general. It is due to Dr. J. C. Saunders that "The London Dispensary of Curing Diseases of the Eye and Ear" was opened in March 25th, 1805. In January 1808, the name was changed to that of the London Infirmary for Curing Diseases of the Eye. After nine years it became obvious that larger and more commodious premises were necessary, and in May 1821 the foundation stone of the London Ophthalmic Infirmary was laid in Moorfields. Dr. William Lawrence and Dr. Frederick Tyrrell were the Surgeons to the Infirmary.

In April 1836 the name of the Institution was changed to "The Royal London Ophthalmic Hospital, Moorfields," when the Duchess of Kent and Princess Victoria became Patronesses. It will be of interest to ophthalmic surgeons working in India where quackery is still rampant that in the eighteenth century ophthalmology was the province of a set of ambulant practitioners who toured the country accompanied by all the apparatus of shameless advertisement, couching cataracts and selling infallible salves and remedies.

It was with such prating mountebanks that Saunders ran the risk of being confused when he devoted himself specially to the treatment of eye disease. Benjamin Travers succeeded Saunders, who was demonstrator of anatomy at Guy's Hospital and Surgeon to the East India Company. In 1819 the Honourable Directors of the East India Company became impressed by the great prevalence of eye diseases in India, and applied to Travers in the matter. He advised establishing eye institutions in India. The advice was accepted and Mr. R. Richardson, one of the Company's Surgeons who had studied ophthalmology under Travers, was sent to Madras where he founded "The Madras Eye Infirmary." So successful was the work of the institution that in 1824 two other surgeons who had studied at the London Eye Infirmary were sent out to India. Mr. C. J. Egerton went to Calcutta and Mr. Jeafferson to Bombay, where each founded an Eye Hospital.

In 1814 Travers found that his work was too arduous and William Lawrence was appointed to the staff. He later became Sir William Lawrence, Bart., F.R.S., and the greatest ophthalmic surgeon of his time, as well as being a leading general surgeon. Tyrrell and Scott were the next ophthalmic surgeons appointed to the staff. The former's memory is enshrined by a blunt hook which he introduced for the operation of making an artificial pupil which is still known as "Tyrrell's hook." The latter is best remembered in general surgery in connection with his treatment of joints and chronic ulcers of the leg: "Scott's dressing" and "Scott's ointment" are still well known. It is said of him that no man lost vitreous humour more frequently during cataract operations, at which he was invariably annoyed, ascribing it to "fluidity" of that body.

Critchett and Bowman joined the staff of the Hospital as Assistant Surgeons in 1843 and 1846 respectively, and afterwards were to make such advances in the science of ophthalmology. Bowman was the first surgeon to use chloroform in cataract extraction, which was the general custom up to the time of the introduction of cocaine in 1884. With the introduction of anaesthesia many new operative procedures on the eye were invented. Exsection of the eyeball was at one time a formidable operation and only resorted to in the case of malignant growths. The operation of removal of the eyeball out of its capsule originated with an Irish anatomist, O'Ferrall, and Bonnet in France was first to put it into practice in 1842. In 1851 Von Graefe, Donders and

Bowman, who were destined to revolutionize the practice of ophthalmology, came together in London and started an intimate friendship which lasted for the rest of their lives. Iridectomy for glaucoma according to Von Graefe's method was first done at Moorfields in 1857. The ophthalmoscope was invented by Von Helmholtz, an army surgeon, in 1857.

In 1857 Streathfield joined the staff of the Hospital and is remembered to this day by the lid operation called after his name. In the same year the first clinical assistants were appointed and included amongst others Jonathan Hutchinson. The first English journal devoted specially to ophthalmology originated with the medical staff of Moorfields Hospital and was called *The Ophthalmic Hospital Reports*. It first appeared in October 1857.

Jonathan Hutchinson was appointed to the staff in 1862. He was described as "the greatest general practitioner in Europe" and also as the "universal specialist."

Waren Tay joined the staff in 1877 and Nettleship in 1882, both of whom had worked as clinical assistants to Jonathan Hutchinson. With the advent of Lister's great discovery of germs being the cause of putrefaction in wounds, ophthalmic surgery took on a new phase. Couper who joined the staff of the Hospital in 1866 was one of the first and most ardent disciples of the Listerian doctrine.

Pasteur's researches in fermentation and putrefaction led to the discovery of the various types of bacteria, and in 1884 incubators and bacteriological apparatus were installed in the pathological laboratory at Moorfields. Lawford who was curator of the museum at Moorfields was one of the first to detect Koch's bacillus in the tissues of the eye.

In 1884 cocaine was first used in England and the first operation performed under its influence was a tattooing of the cornea by Marcus Gunn.

With new ideas which arose out of Florence Nightingale's teaching and with the outcome of bacteriological investigations, the general principles of hospital management became completely changed, and it became obvious in 1884 that the original Moorfields Hospital could not be converted into an up-to-date institution. But it was not till 1897 that the foundation stone of the present Hospital in the City Road was laid and in 1899 it was opened for the reception of patients.

Other distinguished ophthalmologists of more recent date who were on the staff and whose names go down to posterity were Tweedy, Nettleship, Marcus Gunn, Standford Morton, Treacher Collins, Holmes Spicer and Worth.

The perusal of this book will certainly prove that Moorfields Eye Hospital has justified its existence, and to the able members of its staff who have been largely responsible in the great developments of the science of ophthalmology the world in general owes a deep debt of gratitude. The book is entertaining and instructive, and we cordially recommend it to those interested in ophthalmology.

E. O'G. K.

"DEVILS, DRUGS, AND DOCTORS": THE STORY OF THE SCIENCE OF HEALING FROM MEDICINE-MAN-TO-DOCTOR.—By H. W. Haggard, M.D. London: W. Heinemann (Medical Books), Ltd. 1929. Pp. XXII plus 405, with 131 illustrations and 15 plates. Price, 21s. net.

THIS, "the story of the science of healing from medicine-man to doctor," from the pen of the Associate Professor of Applied Physiology, Yale University, is a general account for the layman, unburdened with technical quotations that might have made many points clearer to the profession. The result is almost light reading, but of attention-gripping interest.

The book opens with four chapters on obstetrics from the earliest times up to the recognition of the cause though not the organism of puerperal fever. The impression left with us is one of wonder that between the time when human parturition, as in primitive races even yet, was attended with little more danger than

among the other mammals, and the development in the last century only of modern methods of midwifery, the then population of Europe did not completely cease to exist. Nothing could more lucidly express the state of affairs than the description, and illustration, of "baptismal syringe" of the Seventeenth Century, for use in the case of an unusual presentation, prior to the discovery of even "podalic" version. There follows an account of the discovery of anæsthetics which is so much weighted towards its obstetrical aspects, that it might well have been included in Part I.

Part III deals with the "progress of surgery," and deals in two chapters with the growth of anatomical knowledge, the primary essential surgery engendered by the continual state of warfare of the Middle Ages, through the growth of the nursing profession up to Lister's surgical application of Pasteur's discoveries.

Part IV deals with the great epidemic diseases, plague, cholera, smallpox, and syphilis. In connection with the latter, most interesting historical records are given of its spread through Europe, assuming, though with some reservation, its New World origin. True to the American School, the author apparently holds with "treponism," and suggests that the syphilis of the Old World is the yaws of the New, or a strain thereof of enhanced virulence. A most interesting quotation from Asture, physician to Louis XIV, shows how, following Varro, others speculated on the micro-organismal nature of this and many other diseases in pre-Pasteurian times.

Part V deals with the "healing art" from the days when it was literally an art, up to the pioneers of modern medicine in the last century. We are taken through the various aspects of faith healing and osteopathy, and in the case of the reviewer at least, for the first time obtain a clear idea of the origin and tenets of such cults as Christian Science. The author next deals with drugs and prescriptions, with a wealth of illuminating illustrations, and passes to the inevitable reaction against the enormous and useless pharmacopœia and posology of the Eighteenth Century and earlier as expressed by homeopathy. Here he appears, and perhaps rightly, somewhat sympathetic, for, as he points out, even to-day, or rather prior to the first synthetics and endocrine extracts, what was there in the armamentarium of even the seniors still in practice, other than quinine and mercury, that was in any sense a specific. We finally end with a brief chapter on the place of medicine in modern civilization, in which we hear, for the first time, and all too briefly, of Morgagni, the first real pathologist, whom the reviewer had only heard of previously through failing, anywhere in this country, to obtain a reference in a journal bearing this great man's name as its title. One could wish that details of Morgagni and his work had been given in Section III, at the end of the "Anatomy."

The illustrations throughout the book are reproductions of mediæval woodcuts and paintings, caricatures by Hogarth, and the like. If it is stated that (p. 244) pictures of "Bloody" Mary of England show clearly the stigmata of congenital syphilis, one wonders what type of neurotoxis is indicated by the photo of Mrs. Mary Baker G. Eddy opposite p. 318. It would be interesting to have had the diagnosis of her countryman Harrower on the particular endocrine deficiencies that are indicated by the portrait!

A few minor points call for criticism. The "root" of an orchid that in shape resembles a testicle is not a root at all, but a pseudo-bulb on the stem (p. 352); whilst on p. 368 the description of acid-fast and Gram-positive bacilli could have been made much clearer without more than a few extra sentences. With one point, above all, that is insistent throughout the book, we are in the fullest agreement. The future lies with preventive rather than with curative medicine. To all medical men interested in the dark beginnings of their profession, and in the few great names that dragged it within living memory from the slough of 2,000 years, we recommend this book.

R. S. W.

THE EXTRA PHARMACOPŒIA OF MARTINDALE AND WESTCOTT. VOL. II. 19TH EDITION.
Revised by W. H. Martindale, Ph.D., F.C.S.
London: H. K. Lewis & Co. Pp. 759 plus
XXXVIII. Price, 22s. 6d.

THIS very well known and extremely important volume must be the constant companion of very many of our readers. The amount of information compressed within its relatively small compass is amazing; it contains in general supplementary information in *materia medica* to Vol. I, microscopical, chemical, and biochemical methods of diagnosis, analysis and assay, and is a volume of extreme value to medical practitioners, pharmacists, analysts, and others. In his preface to the present edition Dr. Martindale complains of the overwhelming bulk and character of the medico-scientific literature of to-day, and in some instances he prefers more established and tried older methods than more recent and dubious ones. Nevertheless, the book has undergone ruthless pruning in order to keep down its compass, whilst large sections of new matter have been added. The volume, in brief remains what it always was, one absolutely essential to the physician and laboratory worker, for nowhere else will he find so much information in so small a compass. Yet we would entirely agree with Dr. Martindale's criticism of present-day medico-scientific literature; there is far too much of it. A research worker who publishes twelve papers a year should be penalised; quality and not quantity of research output is what is wanted, whilst a stringent censorship of medical journals is badly wanted in this respect.

The nineteenth edition of this well known work reflects the very great strides which have been made in chemical, pharmaceutical, and medical research during the four years since the previous edition. Yet, "we are inclined to think that many new remedies—including those with vast apparent success—are advocated (to-day) without sufficient proof of utility" writes Dr. Martindale. "We are, of course, by no means averse to pharmacological deductions; indeed, the volume under consideration is largely concerned with experimental research in many fields."

Turning to the many new features of the present edition, these are so numerous that we have not the space in which to deal with them, but the more striking deserve notice. The new methods for the biological testing of toxicity of the organic arsenical derivatives, as adopted by the Medical Research Council and the League of Nations Commission, are fully detailed. The recent work on the toxicity of carbon tetrachloride is reviewed, and it is noted that many workers have gone back to the use of thymol in ankylostomiasis. A review of the value of different methods for the assay of digitalis is included. B. P. liquid extract of ergot is almost valueless. Iodine deficiency is a subject on which much new information is included; recent work in New Zealand shows that iodine deficiency is almost certainly the most important factor in the production of goitre. A simple procedure for iodine estimation, which involves the use of only five chemical reagents, is given. Chlorination of water supplies does not appreciably interfere with their iodine content, but on the other hand white flour contains fifteen times less iodine than the germ of wheat.

The use of iodinol, 40 per cent., for x-ray work in connection with diseases of the bronchi and urethra is outlined. Emetine poisoning is noted, and an assay process given for mercurochrome. Recent work upon the whole group of the vitamins—A, B, C, D, and E—is the subject of ten pages of closely printed matter, followed by a general section on foodstuffs. Liver function tests, mannitol-quinine for injection, and the biological assay of strophanthus are further subjects dealt with.

Animal organotherapy naturally figures largely in the book; also the methods for recognition of organic chemicals, and the tests for the antiseptic power of different substances. Radiology is dealt with under the headings of dosage, ultra-violet light, diagnosis, treatment, dangerous effects, protective materials, high frequency current, diathermy, Finsen light, heliotherapy, etc. Radium is the

subject of a further section; and the author regards the present monopoly with regard to radium as "scandalous and from all aspects to be regretted."

The chapters on the analysis of urine, blood, faeces, and cerebro-spinal fluid have been drastically revised and largely re-written. The subject of milk is exhaustively dealt with; all recent legislation in Great Britain from 1915 to the present date is reviewed, and an immense amount of public health and laboratory information is here included. In the bacteriological notes almost every disease from aene to yellow fever has been dealt with, recent vaccination orders being outlined, and the latest work on smallpox and yellow fever.

A general inspection of this volume leaves one with an impression of the present-day enormous scope, but also confusion, of therapeutic methods in general. The future, we consider, must tend towards more standardization and less "random sampling."

We need add nothing further about this invaluable work, except to say that in its new and latest edition it is as important and valuable a *vade mecum* to a host of workers of different kinds as it ever was, and even better than before.

R. K.

BAILLIÈRE'S SYNTHETIC ANATOMY. PART V. THE LEG. PART VI. THE FOOT.—By J. E. Cheesman. London: Baillière, Tindall and Cox. 1929. Pp. 6 in each part, with 12 plates. Price, 3s. net per part.

We would like to draw the attention of medical students and of surgeons to Parts V (the leg) and VI (the foot) of this very fine work. It is beautifully executed and of the utmost helpfulness. The work consists of a series of drawings in colour on transparent sheets of paper superimposed on one another. By turning over the leaves the student obtains a reconstruction of the parts as they are dissected. The execution of the plates by the author, Dr. J. E. Cheesman, is altogether admirable.

In these two sections the anterior tibial and peroneal arterial systems of the leg are very well brought out, with the branches of these vessels and the medial and lateral plantar arteries of the foot. As in the previously published sections, the text matter is well indexed and this greatly facilitates reference. We can cordially recommend this fine work alike to medical students and surgeons. We have noted a tendency of the pages to stick together in the hot and moist climate of Calcutta, and possibly the publishers can pay attention to this point with regard to copies intended for sale in the tropics.

N. C.

PHYSIOLOGY OF THE CENTRAL NERVOUS SYSTEM AND SPECIAL SENSES.—By Dr. Vazifdar, L.M. & S., F.C.S., F.C.P.S. Fifth Edition. Calcutta: Thacker, Spink and Co. 1929. Pp. 301 plus VII, with 30 illustrations. Price, Rs. 5-4 net.

Physiology of the Central Nervous System and Special Senses by Dr. Vazifdar has already attained some degree of popularity, and the appearance of its fifth edition will be welcomed. Though much new material has been incorporated, the author has not attempted to cover the whole field of the physiology of the central nervous system and indeed that would have been impossible in such a small book, but has restricted his attention to the special requirements of medical students. The book is a résumé of the subject treated in exhaustive textbooks and the author cordially admits in the preface that it is meant to be used as an adjunct to other textbooks. Nevertheless in the book there are original touches which enhance its value. The tables are admirably arranged and give a wealth of information in a nutshell. The diagrams are all executed in line-drawing, are very clear, and are quite easy to reproduce and to remember. The discussions on applied physiology in small print in almost every chapter of the book will appeal to students and physicians alike, inasmuch as these will help them to the clear and scientific understanding of the various nervous diseases. The consideration of the autonomic nervous system does not fall within the

province of the book, but this is so intimately connected with the central nervous system in the minds of the readers that a chapter devoted to the autonomic system would certainly have been appreciated.

On the whole the book is admirable and is very well adapted to the needs of medical students and practitioners for ready reference and guidance.

R. N. C.

FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE.—Transactions of the Seventh Congress, British India, 1927. Vol. II. Published by Thacker's Press & Directories, Ltd., Calcutta. Edited by Lieut.-Col. J. Cunningham, C.I.E., I.M.S. Pp. XVI plus 871, with numerous plates and figures in the text.

We have previously dealt so fully with the Seventh Congress of the Far Eastern Association of Tropical Medicine, held in Calcutta in December 1927, that our note with regard to its *Transactions* must necessarily be brief. The three volumes, when completed, will be an immense addition to the literature on tropical medicine, for there is hardly any field of tropical medicine and hygiene with which the Congress did not deal. The second volume is a quarto volume of 871 pages, admirably illustrated and edited, and very well got up and published. It contains the papers and discussions with reference to plague, cholera, dysentery, sprue and intestinal infections, bacteriophage, leprosy, tuberculosis, bacteriology, typhus-like diseases of the tropics, protozoology, and—above all—malaria. There is here a wealth of information for the student of tropical medicine and hygiene.

Of pre-eminently important papers in this volume one would single out Colonel Mackie's address on the present position of the world-plague problem; Khan Bahadur Dr. N. H. Choksy's paper on an unrecognised type of plague (one associated with extensive necrosis of the subcutaneous tissues); Colonel Russell's studies in the epidemiology of cholera—a summary of many years of investigation and analysis of statistics; Colonel Dunn's account of the successful anti-cholera measures at Hardwar; the reports on the investigation of sprue from the Haffkine Institute, Bombay; Dr. d'Herelle's studies of bacteriophage; Dr. Muir's survey of leprosy in the tropics—a series of several papers dealing with different aspects of the leprosy problem; the papers on tropical skin diseases from Colonel Acton's department; and, above and beyond all, the section on malaria.

Very important are the resolutions passed with regard to the control of plague and malaria. Both lay down a programme for future study and research. Members who were present at the discussions in the malaria section will remember that there was a considerable difference of opinion between those who advocated malaria control by extensive quinine distribution and mosquito-swatting, and those who held that the only way to control malaria was by anti-mosquito, anti-larval, and even anti-species measures. This discussion is here given in full, and is of very great importance.

The *Transactions* will be issued to members of the Association as they are published. Whether other copies will be available for purchase, we do not know; but there is no large medical library in India which should be without a set. In the course of time the work summarised in this wonderful volume will be incorporated in textbooks of tropical medicine; in the meantime the medical man working in the tropics would do well to secure a copy of the *Transactions*, and read or glance through it, for they contain a wealth of new information with regard to tropical diseases.

R. K.

THE LAW RELATING TO MEDICAL, DENTAL, AND VETERINARY PRACTICE.—By Fred Bullock, LL.D., Barrister-at-Law. Pp. 317. London: Baillière, Tindall and Cox. 1929. Price, 12s. 6d.

THIS is a most important book, very well got up and published, and issued at a very reasonable price. The present laws in Great Britain relating to medical practice are the outcome of four centuries of experimental legislation, and are the models upon which most

medical legislation in the British Empire has been founded. Further, the book has been revised by Colonel Norman C. King, Registrar of the General Medical Council, and by Dr. Alfred Cox, Medical Secretary to the British Medical Association. It is therefore fully authoritative.

After an introductory chapter, the author first deals with the subject in historical sequence, showing how physicians and surgeons came to replace the old time barber-surgeons, and veterinary surgeons the farriers and marshals of olden days. There is very much of interest in this section, including an account of the granting of charters to different London corporations. Next comes an account of the early statutes, dating back to the first Medical Registration Act in 1511. The Lambeth degrees were authorised in 1533, and the first Barber-Surgeons' Company was incorporated in 1540. King Henry VIII unfortunately, amongst his other irregularities of conduct, commenced the granting of special licenses to practise to quacks, and even the ever famous Dr. Caius was unable to prevent an incompetent Franciscan friar from being elected an F.R.C.P. in 1563.

Chapter IV deals with the seventeenth and eighteenth centuries. One of the most important medical enactments was the Surgeons' Charter of James I, in 1605. Harvey's appointment as Physician to the King led in 1618 to a new charter issued to the College of Physicians. The Apothecaries Society had become a trading company by 1684, and called down the caustic comments of Pope on them in 1711; patent medicines were already on the market by 1711.

Coming to the nineteenth century the Apothecaries Act of 1815 marks the first departure in modern legislation. They really aimed at protecting the public from unqualified persons; and a certified apothecary could practise anywhere in Great Britain. The British Medical Association was founded in 1832, and was mainly responsible for the preparation of the Medical Reform Bills. The Medical Act of 1858 set up the General Medical Council and laid the broad foundations of the present-day position. The effects of this Act are fully discussed by the author in a most important section of his book. The Medical Act of 1886 amended certain sections, whilst in 1927 the Irish Medical Practitioners' Act established a separate register for the Irish Free State.

Chapter VI deals with the history of legislation with regard to dentistry. Here the Act of 1878 is the fundamental one, modified by the later Dental Act of 1921. How badly this was wanted is indicated by the fact that it was estimated that at that time about 10,000 unqualified persons were engaged in the practice of dentistry. Chapter VII deals with the veterinary surgeon. Here the history of the subject centres round the "one port of entry" question, and the fundamental Act is that of 1881, later modified by the Acts of 1900 and 1920. In 1923 the present charter was granted to the Royal College of Veterinary Surgeons.

The author next passes to a consideration of the present-day condition of affairs, dealing first with the jurisdiction of the Privy Council. Next comes a most important chapter on professional discipline; here one after another of a series of important and historical cases are cited and explained in their legal bearings. Chapter X deals with unqualified practice. Again the subject is illustrated by many cases quoted and quotations of legal decisions given. Chapter XI deals with the legal rights of qualified practitioners; these concern chiefly the legal right to sue for fees. Chapter XII deals with the legal offence of "professional negligence," and the concluding portion of the book is devoted to the law with relation to lunacy, an appendix quoting certain important sections of the Lunacy Act, 1890, verbatim. A bibliography, a table of the statutes, another of the charters and ordinances, and a third of celebrated and important cases referred to complete the volume.

This book has been badly wanted. It summarises the whole position, commencing with its historical foundation, and leading up to a full description of the present-day position, in a nutshell. It is commendably brief, and commendably well written. It is both of historical

interest and present-day legal importance, and we would heartily commend it alike to medical librarians, those interested in medico-legal work, and barristers. Further, with medical constitutions at the moment very much under consideration in India, it has a special importance for India.

R. K.

CATALOGUE OF LEWIS' MEDICAL AND SCIENTIFIC CIRCULATING LIBRARY. Revised to the end of 1927. London: H. K. Lewis & Co. 1928. Pp. 576. Price, 15s. (to subscribers 7s. 6d.).

Lewis' medical circulating library is to the medical public what Mudie's is to the novel reading one. Founded in 1848, it has been continuously increased and added to since, and now includes all works of any importance, English, American, and foreign (if translated into English) in medicine and allied sciences generally. Individuals, medical societies, research departments, etc., may all subscribe. The terms vary from £1-1-0 per annum for one volume borrowed at a time, to £15 for thirty volumes; subscribers abroad are also required to pay a deposit of not less than half the annual subscription (minimum £1), and an advance of 10s. for postage. Volumes may be retained as long as desired, or exchanged as frequently as desired.

Medical men in India often find special difficulty in securing books to which they wish to refer, and there may be many of our readers who will be interested in this extremely comprehensive catalogue. It will also be of special interest to Indian medical men who are proceeding to Great Britain to take out post-graduate courses of instruction and diplomas.

The address of the firm is H. K. Lewis & Co., 136, Gower Street, London, W.C. 1, and envelopes should be marked "Library."

R. K.

HABITUAL CONSTIPATION AND ITS TREATMENT.—By Dr. M. H. Burnier, M.D. (Lausanne), M.R.C.S. (Eng.), L.R.C.P. (Lond.). Authorized translation by H. Child, M.R.C.S. (Eng.). Pp. 71, with 6 illustrations. London: Baillière, Tindall and Cox. 1929. Price, 3s. 6d.

THIS is an English translation of what is practically an essay, and perhaps its most interesting section is its preface, where the author outlines the usual course of the all too frequent case of habitual constipation; this may end either in the impossibility of emptying the colon without the daily use of a drastic purgative, or an operation for "kinks"; it may cost the patient half a fortune in skiagrams, gastric analyses, and the psychical treatment of "functional derangements."

In the first three chapters the author discusses the pathogenesis and evolution of constipation. Very important here is the discussion on the rôle of purgatives; if irritant they end by abolishing the normal "rectal call" to defæcate and make the patient almost entirely dependent on them. Enemata are better, and are the usual remedy adopted by the sedentary and middle aged,—or alternatively, suppositories. The author, however, believes that direct stimulus to the rectum is the best means of securing a normal evacuation and to this end has designed a special instrument—a "laxor." This is roughly an enlarged pair of forceps with the blades at right angles to the handles: the vaselined blades are inserted into the rectum, and alternately opened and closed by manipulation of the handles, thus stimulating the "rectal call." An account of seven illustrative cases completes the brochure.

Theoretically, we suppose that the author must be right in claiming that what is needed in such cases is a stimulus to the rectum, rather than an irritant applied throughout the whole length of the alimentary canal. If the "laxor" will alleviate what is probably to-day the commonest malady of mankind, owing to our evil civilized habits, we shall expect to see it widely used.

At least the essay has the merits of being novel and interesting.

R. K.

THE EXPECTANT MOTHER AND HER BABY.—By Bodh Raj Chopra, M.B., Ch.B. (Edin.), Lahore. Pp. 157. Edinburgh: W. Green & Son, Ltd. Price, 7s. 6d. net. Obtainable from Messrs. Butterworth and Co. (India), Ltd. Price, Rs. 5-10 net.

THIS little book strikes a new note in medical publications by authors in India. In the first place the author, who is an Edinburgh student, has gone to British publishers, with the result that the book is admirably printed, free from typographical errors, well bound, and well published. Secondly, it is written especially from the Indian point of view whilst the author has a certain forcefulness of personality, which makes the book differ from the usual didactic and impersonal type of book dealing with the subject. Thirdly, he has some most interesting quotations from the *Charak Samhita*.

The book follows in the main upon the usual lines. In the first chapter infant mortality is considered with special reference to Indian conditions. A point of importance here is the author's protest against the wide advertisement of patent nostrums in India; India probably suffers from this evil more than any country in the world. Child marriage and the education of Indian girls are also matters on which there are interesting comments. Chapter II deals with the signs and course of pregnancy; here the dietary instructions for Indian mothers are well put together, and there are special comments on the dangers that may be indicated by bleeding from the vagina early in pregnancy. On pp. 20 and 21 there are delightful quotations from *Charak*; in a woman who lies upon her back, the umbilical cord twines round the neck of the foetus; an expectant mother who frequently engages in wordy warfare will bring forth an epileptic child; a woman who sleeps in an uncovered place or rambles at night brings forth a child that is insane; a woman that is fond of sweets brings forth a child that becomes subject to urinary diseases and obesity; a woman who is fond of pork brings forth a child that is of bloody eyes, or that becomes subject to asthma (food idiosyncrasy, we suppose), or that has hair exceedingly hard. Further, the expectant mother is warned against the practice of blood letting during the months of May and June that is popular in some parts of India.

These words of wisdom are those of a sage of ancient days, but we wonder what basis they have in observed facts. Even a "Western" physician, however, would hardly advise pork for an expectant mother.

In the next two chapters the care of the newborn infant and the subject of infant feeding are discussed. The author is opposed to the Indian custom of delaying weaning until a late period. There then comes a chapter on the wet-nurse or *daia*. This is important, for the author again writes with special reference to Indian conditions. *Charak's* ideal of a wet-nurse is quoted verbatim, and is full of common sense; the proposed *daia* should not be addicted to hunting, gambling, sleeping during the day, speaking ill of others, dancing, singing or instrumental music, or jealousy. Her milk should dissolve completely in water; milk that sinks in water is abnormal.

Subsequent chapters deal with weaning, artificial feeding, the hygiene of infancy, the normal growth and development of the baby, and the common ailments of infancy. The closing chapter—one which largely owes its inspiration to the teachings of Dr. John Thomson of Edinburgh—adds greatly to the value of the book, since it deals with the care of the mentally deficient child, the early signs of mental deficiency, and the home care of such children. The author's remarks on what "cow's milk" is like in India are very much to the point unfortunately, though one can hardly agree with him in attributing tuberculosis in childhood in India to milk; it is far more often due to the human strain of Koch's bacillus. In a second edition, also, one would like to see the section on infantile diarrhoea and dysentery expanded; dysentery in infants in India is usually of bacillary type, the stools are very infectious, and a nursing mother suffering from the disease, or one who has to prepare the family meals, is often the unconscious agent of wholesale spread of the infection.

We have devoted some considerable space to this book, but we consider that it is a very sound one, and that it will have a special appeal to workers in child welfare in India and to educated Indian mothers.

R. K.

HEAT PYREXIA, NO HEAT STROKE, NO HEAT FEVER.—By Lieut.-Col. C. J. McCartie, M.A., M.D., M.Ch., I.M.S. (ret'd.). Pp. 27. Dublin: Browne and Nolan Ltd. Indian Agents: Messrs. Thacker, Spink and Co. Price, 12 annas.

THIS is an interesting little essay, whose main contention is that there is no such thing as sudden sunstroke. In cases of apparently sudden heat hyperpyrexia there is always a prodromal phase during which the temperature of the body is rising; and the one special aetiological agent in sunstroke is the utterly unsuitable clothing which British troops wear in the tropics. Whilst the author's suggestions are interesting, either he or his printers are terrible "capitalists"—these are, for example, 8 unnecessary capital letters in four lines on the first page. Such over-emphasis irritates rather than attracts the reader. There are also such printer's errors as "Ossler" for "Osler," and "Mesopotamia" for "Mesopotamia."

Colonel McCartie, however, in our opinion is entirely right in his criticisms of the type of clothing advocated for European troops in the tropics. The doctrine of the flannel shirt for the British Tommy he condemns out of hand, also the cognate doctrine of "flannel next the skin," and that atrocity—the "cholera belt." It is a well known fact that British troops in India suffer far more severely than do British civilians from sunstroke; the author finds the explanation for this difference in the difference in their clothing; the civilian wears a twill shirt and a cotton suit in the hot weather, the Tommy a flannel shirt, and possibly a tightly buttoned up kahi serge tunic over it. Dress reform (for males) in the tropics is in fact the essence of his essay, and we are in complete agreement with him.

On the other hand, we wonder whether the author has paid sufficient attention to concurrent diseases as aetiological elements in the causation of sunstroke. This condition was extremely prevalent during the war in Mesopotamia, yet many of these cases were ones of malaria or of paratyphoid fever, in which hyperpyrexia set in after hours of exposure to a burning sun.

The problem of heat hyperpyrexia is especially one for the military medical authorities in India, as also one on which we would welcome information. Colonel McCartie is admittedly an enthusiast for cool clothing in the hot weather in the tropics. The Englishwoman in the tropics is already ahead of him. "Dress reform" means something more important in the tropics than in the temperate zone; it has a special bearing on the health of the immigrant white races and on the problem of heat hyperpyrexia.

R. K.

THE HYGIENE OF MARRIAGE.—By Isabel E. Hutton, M.D. Second Edition. Pp. 125 plus X. London: William Heinemann (Medical Books), Ltd.

OF the very many books on sex hygiene for lay persons this is probably the best, for it is simply and clearly written, and the difficult subject is handled without offending good taste. "I hope" writes the author in the preface to her first edition "that in this work parents will find a suitable book to put into the hands of their sons and daughters who are about to be married..... The matter has been simply treated, nevertheless it is quite scientific and no attempt has been made to embellish it."

The second edition contains new chapters or sections on the menopause and on menstruation. A new chapter on sterility has also been added, and this is very well written, for it contains clear indications as to when to consult a doctor. The chapter on birth control has been amplified. In this connection we are entirely in agreement with the author in her remarks in the preface; birth control has become a commercial business, and present-day methods are not based, as far as one knows,

on scientific evidence. This problem is one which the medical profession will have to study sooner or later, for it cannot be left to lay investigation.

The second edition of this book now covers the whole period of reproductive life, including the menopause. It is inevitable—even desirable—that there should be a demand for books of this type; the one under consideration is the best that we have seen. The author writes that "she has been amazed to find that there are many people who have been married for several years who are in great need of help over their sex life, more especially during and after the 'change of life.'" Medical experience will bear her out, and the book is one of which we cordially approve.

R. K.

Annual Reports.

THE ROCKEFELLER FOUNDATION: A REVIEW FOR 1928. BY GEORGE E. VINCENT, PRESIDENT OF THE FOUNDATION. Pp. 54; PROFUSELY ILLUSTRATED. PUBLISHED IN NEW YORK.

SOME idea of the manifold activities of the Rockefeller Foundation may be gathered from the following synopsis at the beginning of this report on its work in 1928:—

During 1928 the Rockefeller Foundation, in disbursing from income and capital \$21,690,738, (1) contributed to the development of medical sciences through provision of funds for land, buildings, operation, or endowment for eighteen medical schools in fourteen countries; (2) provided for the support of the Peking Union Medical College; (3) made minor appropriations for improving premedical instruction in China and Siam, for operating expenses of seventeen hospitals in China, and for laboratory supplies, equipment, and literature for European medical centres which are still feeling the after-effects of the war; (4) through small grants assisted certain departments of medical schools in France, Italy, and Ireland which offer exceptional facilities for graduate study; (5) continued to contribute towards the advancement of the biological sciences in institutions in four countries; (6) assisted the development of professional public health training in eight schools and institutes in seven countries and in twelve field training stations in the United States and abroad; (7) gave aid to fifteen nurse training schools in ten countries; (8) helped Brazil to combat a new outbreak of yellow fever; (9) continued studies of that disease on the West Coast of Africa; (10) took part in malaria control demonstrations or surveys in six of the American states and in eighteen foreign countries; (11) continued contributions towards the emergency budgets of eighty-five county health organizations in seven states of the Mississippi flood area; (12) aided the governments of twenty-one countries in fighting hookworm disease; (13) gave funds to organized rural health services in 191 counties in the United States and towards state supervision of such services in fourteen states in that country, and assisted in local health work in twenty-three foreign countries; (14) aided in the establishment or maintenance of certain essential divisions in the national health services of twenty-three foreign countries and in the state health departments of nineteen American states; (15) provided, directly or indirectly, fellowships for 802 men and women from forty-six different countries, paid the travelling expenses of sixty-one officials or professors making study visits in the United States or abroad and provided similar opportunities for 127 nurses and other public health workers; (16) contributed to the work of the Health Organization of the League of Nations through the support of international interchanges of public health personnel and the development of a world-wide service of epidemiological intelligence and public health statistics; (17) lent staff members as consultants to

many foreign governments; (18) made surveys of health conditions or of medical or nursing education in five countries; (19) collaborated with the Rockefeller Institute for Medical Research in field studies of respiratory diseases and verruga peruana; (20) assisted in mental hygiene projects in the United States and Canada, in demonstrations in dispensary development, research, and teaching in hospitals and clinics in New York City, and in numerous other undertakings in public health, medical education, and allied fields.

The Rockefeller Foundation was originally established in 1909 for the control of hookworm disease in the United States, as the Rockefeller Sanitary Commission. It was later reorganized as the International Health Board. The temporary anti-hookworm campaigns in the southern United States, however, have now expanded into permanent official rural health organizations, whilst multifarious teaching and public health organizations have been created all over the world. One of the most important decisions came to in 1928 was to create a new public health institute under the Government of India at Calcutta; this new building will be adjacent to the Calcutta School of Tropical Medicine, and the staff of both institutions will train students both for the D. T. M. diploma of the Bengal Faculty of Tropical Medicine and for the D. P. H. diploma of Calcutta University. Further, up to December 1928, the Rockefeller Foundation had provided no less than 3,187 fellowships—a most important part of their programme.

A reorganization of the central and controlling Board took place in 1928, resulting in the creation of two special central organizations, the General Education Board for the United States, and the world-wide Rockefeller Foundation itself. The combined resources amount to \$203,000,000, with outstanding obligations of \$35,000,000.

Turning to local activities, the year saw important developments at the Lyon Medical Centre. Eighteen medical schools, from Edinburgh to Beirut, received financial assistance. The Peking Union Medical College is well on the way towards autonomy. Health education everywhere, both in the laboratory and in the field, was subsidized. In May 1928, yellow fever which it was hoped in 1927 had been abolished from South America, reappeared in Rio de Janeiro—108 cases with a 50 per cent. mortality. This outbreak, however, is now well under control again. Yellow fever was also studied in West Africa and in the Rockefeller Institute for Medical Research in New York. The year saw the tragic deaths of Professor Noguchi and Dr. W. A. Young from this disease in the field; also the proof that yellow fever is due to a filterable virus, and not to the supposed *Leptospira icteroides*, and the demonstration of the susceptibility of the monkey *Macacus rhesus* to the disease. The American and African viruses have been proved to be identical.

"Thinking like a malaria mosquito" is an interesting section of the report: the malariologist must learn to think like a mosquito. The various differing views with regard to methods of malaria control are discussed. Essentially, however, malaria is a local problem, and what suits one area may not suit another. Hookworm disease is regarded by the Foundation as "the advance agent of public health organization;" and in 1928 anti-hookworm campaigns were carried out in no less than fifteen different countries. Health organizations were maintained in the flooded areas in the Mississippi Valley; and local health programmes developed in many countries from Warsaw to Shanghai. Of fellowships granted during the year, 218 were in advanced training for the promotion of teaching and research, and 584 designed to prepare men and women for specified positions in medical schools, schools of nursing, health organizations, etc. The services of experts were lent freely to foreign countries. Publications were more numerous than ever. A special investigation during the year was undertaken into the value of Calmette's vaccination against tuberculosis.

In brief, a most interesting report on a most wonderful year of work.

THE SIXTY-FIFTH ANNUAL REPORT OF THE DIRECTOR OF PUBLIC HEALTH, MADRAS, FOR THE YEAR 1928. BY CAPT. N. R. UBHAYA, L.R.C.P. & S., D.P.H., ACTING DIRECTOR OF PUBLIC HEALTH, MADRAS, SUPDT., GOVT. PRINTING, MADRAS. PRICE RE. 1-4-0.

THIS report is well summarized in the covering Government resolution from which we have taken the following abstract. One regrets very much that it is the last report on the work of Lieut.-Col. Russell, I.M.S., whose many years of public health work have resulted in so much progress in Madras Presidency.

The total number of deaths (1,080,744) from all causes during the year was the highest on record for the quinquennium, and was more than the quinquennial average (1,026,723) by about 54,000. As compared with the previous year there was an increase of about 83,000 deaths during the year under review.

Cholera.—With the exception of the Nilgiris and Malabar, which may be said to have been practically free, every district was infected. There was a marked increase in mortality from 35,334 during 1927 to 57,677. The death-rates for 1927 and 1928 were 0.9 and 1.4, respectively, against the quinquennial average of 0.8 per mille. The epidemic was severe in nine districts with mortality rates over two per mille. Compared with 1927 the increase in the death-rate was marked in the districts of Cuddapah (+ 6.6), Kurnool (+ 3.2), and Chingleput (+ 2.4) and the largest decrease was recorded in Rāmnād. Eighteen municipalities were entirely free. The minimum and maximum incidence were severally recorded during the second and third quarters of the year. It is observed that effective measures were taken to combat the disease. Anti-cholera inoculation during the year gave ample proof of its protective value. The Director of Public Health points out, however, that the present methods of combating the disease are only palliative, and if the disease is to be combated effectively, the authorities should attend promptly to the provision of a protected water-supply wherever cholera is likely to break out as an epidemic. It is equally necessary that adequate sanitary arrangements should be made at festival centres and that irrigation channels should be kept in a sanitary condition.

Smallpox.—No district was free from smallpox, though there has been a progressive decline in mortality during the last three years. Seven thousand six hundred and eighteen deaths were recorded as against 7,781 during 1927. The death-rate was 0.2 per mille, the same as during 1927, against the quinquennial average of 0.4 per mille. While 48 municipalities recorded a death-rate of 0.2 during the previous year, 43 recorded 0.4 per mille in 1928. More than 50 per cent. of the mortality occurred in Madras, Calicut and Mannārgudi. Sixty-four rural towns registered 306 deaths from smallpox against 377 in 72 towns during 1927. The mortality classified according to age distribution showed that the incidence was as high as 40 per cent. in the age period under one. It is therefore clear that primary vaccination still requires great improvement. South Arcot continued to return the largest number of deaths in the Presidency. The local bodies in the district should employ adequate vaccination staff. The Director of Public Health brings again to the notice of the Government that delay occurs in the notification of the disease. It is needless to emphasize the importance of sending prompt intimation of any outbreak of the disease to the Public Health Department. Collectors should realize that failure to report outbreaks and delay in the submission of reports permit the establishment of epidemic conditions before preventive measures can be initiated.

Plague.—The number (2,106) of deaths from plague during the year under review approximated to that (2,014) in 1925, which was the lowest on record since the disease first made its appearance in the Presidency and it represents a death-rate of 0.1 per mille, the same as the quinquennial average. Eighteen districts were entirely free. The largest number of deaths was

as before in Madura and Bellary which were responsible for about 67 per cent. of the total mortality in the affected districts. Of the 12 municipal towns affected, Hindupur which had been free for a long time, recorded the highest death-rate of 3.9 per mille, while in Hospet, the most plague-ridden town in the previous years, the rate fell from 4.7 to 0.3.

Malaria.—The appointment of a special officer to investigate the conditions regarding malaria in the Presidency, the free distribution of quinine in specially malarial tracts and the adoption by the local bodies concerned of the measures suggested to combat the disease, prove that the malaria problem is beginning to be dealt with seriously.

With the exception of Cuddapah, the municipal areas in which the Special Malaria Officer made investigations did not show any appreciable evidence of malarial endemicity, the spleen rate in each case being 2 per cent. or less. The case is, however, different in the rural areas. Puttur, Koilkuntla, Siruguppa, Talaman-chipatnam and Humma are all reported to be typical areas of hyperendemicity.

The scheme of free distribution of quinine as judged from its progress during the year under review was successful. Quinine treatment is beginning to be popular. The Government have under consideration a proposal to reduce the price of quinine below the commercial price as a public health measure.

Relapsing fever.—Coimbatore, Madura and the Nilgiri districts continued to be affected, but the infection was not severe in any of them. These districts registered 119 deaths from this cause. The establishment of the disease in Udamalpet and Dhārāpuram taluks in the Coimbatore district should receive the early attention of the local bodies concerned and the Public Health Department, and vigorous measures should be adopted to combat the disease.

Respiratory diseases.—There was a marked increase in mortality during the quinquennium. The total deaths registered amounted to 90,012 compared with 81,227 in 1927, representing rates of 2.2 and 2.0 per mille, respectively, the quinquennial average being 1.8. The Government await with interest the results of the detailed investigation of the statistics of individual districts and towns, proposed by the Director of Public Health to determine the causes of the increase.

Hookworm.—The Ankylostomiasis Campaign was taken over entirely by the Government from the International Health Board of New York from 1st April, 1928, and incorporated as an integral part of the activities of the Public Health Department under the designation of the "Rural Sanitation Campaign." One thousand five hundred and five lectures were given to an audience of over two lakhs and 62,914 treatments were given by the campaign staff in schools, villages and on estates, while the medical officers in charge of hospitals and dispensaries treated 144,475 persons. The experimental work begun at the Madras Presidency Penitentiary in September 1926 was continued throughout the year under review. The campaign staff engaged in the prevention of soil pollution with a view to secure as great a measure of success as possible utilized to a great advantage the dozen earth-boring tools purchased for making deep borehole latrines. Local bodies also showed greater interest in this branch of work. The Health Officer, Planters' District, and his staff visited 63 estates in the Nilgiri and Wynad districts and administered a total of 14,337 anti-hookworm treatments.

Registration of vital statistics.—Though as a result of the reorganization of the Public Health Department considerable improvement has been effected in the registration and compilation of vital statistics, yet the work is reported to suffer from serious defects which only an earnest endeavour on the part of the local authorities can remedy. One of these defects is stated to be the incomplete enumeration of births and deaths, especially in the rural areas. In these areas about 76,500 births and 23,200 deaths which were not registered were detected during the year by the District Health staff. Collectors of districts are requested to instruct the local

revenue authorities to take measures to remove this defect.

The Government have already impressed on the Collectors the necessity of extending the provisions of the Madras Registration of Births and Deaths Act (III of 1899) to all the rural areas in this Presidency. In spite of this no appreciable progress was made in that direction in 1928. Collectors are requested to give this matter their serious attention and submit proposals for the extension of the Act to all rural areas or at least to all villages with a population of 2,000 and above. It is very unsatisfactory that although registration is compulsory in municipal areas, as many as 30 per cent. of the municipalities returned birth-rates less than 35 per mille, the worst instances in this respect being Tiruvārūr, Erode, Nandyal and Srirangam. The Tiruvārūr Municipal Council is reported to be very refractory to criticisms and suggestions for improvement and the council is reminded that it is open to the Government to substitute coercive for persuasive methods. The municipal councils of the towns named above should lose no time in taking the necessary steps to improve this important branch of municipal administration. It is further reported that the birth and death registers are full of irregularities of omission and commission which seriously affect the value of the records. In G. O. No. 1243, P. H., dated 10th May, 1929, the Government have published for general criticism draft rules prescribing the minimum educational standards for the municipal birth and death registrars and these rules will be confirmed shortly. The Government trust that when these rules come into force many of the defects now noticed will cease to exist. The Director of Public Health brings to notice that incompleteness of vital statistics returns still prevails to an appreciable degree in the districts of Guntūr, Nellore and Tanjore.

The recorded birth-rate of the Presidency rose from 36.5 to 37.4 per mille against the estimated Presidency average rate of 42.5. Thirteen districts reported increases which were most marked in Malabar, Gōdāvari East, Madura and Rāmnād. Ganjām and Cuddapah recorded the largest decreases. The birth-rates exceeded the death-rates in all districts except Cuddapah, Kurnool and Madras. The registered birth-rate in municipalities rose from 39.4 to 40.1, while that in rural towns showed slight decrease, viz., from 36.7 to 36.4. The highest birth-rates in municipalities were recorded in Salem, Kodaikānal, Guntūr, Chingleput and Bōdinayakkauūr, while the lowest rates were reported from Erode, Tiruvārūr, Nandyal, Palacole and Srirangam. The low birth-rate in these five municipalities is attributed to defective registration, which in spite of criticisms in the past has received little attention from the municipal authorities concerned.

Death-rate.—The recorded death-rate for the Presidency rose from 24.3 to 26.4 per mille according to the crude rates calculated on the 1921 census population, and it was 23.5 per mille when calculated with reference to the assumed natural increase in population. The death-rates in 18 districts show increases when compared with the previous year, the largest variations being recorded in Cuddapah and Kurnool. The largest decrease in the death-rate was in Ganjām. The recorded death-rates for municipal and rural areas rose from 30.6 and 24.0 to 33.7 and 25.2, respectively. In six municipalities, namely, Erode, Berhampur, Palacole, Vellore, Ellore and Vāniyambādi, the death-rate was below 20 per mille, and the absurdly low rate reported from Erode (14.5) and Berhampur (15.5) is attributed to defective registration. The attention of the municipal councils concerned is drawn to this defect and they are requested to rectify it. The infantile death-rate during the year under review rose from 175.4 to 184.2 per mille of the registered births, the maximum being recorded by the Kurnool district (235.6) and the minimum by Rāmnād (140.0) and rates above 200 were recorded by five districts, namely, Mettūr, Kistna, Gōdāvari West, Guntūr and Kurnool. Marked decreases occurred in Madura and Trichinopoly. The rate also rose in municipal towns from 186.7 to 202.5, very high rates being recorded by Palni, Masulipatam, Guntūr,

Vizagapatam and Madras. The results set forth above prove conclusively that preventive measures are very urgently needed in these towns. The municipal councils concerned are requested to take very early steps to bring about improvement in this direction.

Maternity and child-welfare.—There was a further and marked increase in the number of deaths registered in the Presidency as being due to or arising from child-birth, from 7,902 to 11,150. The increase is, however, attributed in part to improved registration of causes of deaths. It is regrettable that only 3.2 per cent. of the confinements in rural areas received skilled aid. Although the Government have repeatedly directed that local bodies should pay more attention to the health of the mother and child, it is disappointing that there was no appreciable response. There were in 1928 only 69 maternity and child-welfare centres in the Presidency, though this was 14 more than in the previous year.

The Government are glad that the preliminary investigation of this problem was undertaken during the year in Madras, Madura, Trichinopoly and Coimbatore. They trust that further investigation will enable the Public Health Department and local bodies to deal with the problem efficiently and successfully. In this connection the Government congratulate Dr. Adishesan on the useful research work done by him during the year.

Propaganda.—With the establishment of the Propaganda section in the office of the Director of Public Health, health publicity in the Presidency is steadily developing. The Irwin cup for the best conducted Health Week in India was awarded to the Pnukonda Union.

During the year 108,997 lectures (excluding magic lantern demonstrations) were delivered in over 50,000 centres to audiences totalling over 6½ millions, representing an increase of about 17,200 lectures, 9,000 centres and an audience of 900,000 as compared with the previous year. The cinema was employed by a few local bodies to educate the masses in health problems. The total number of cinema shows on Public Health subjects was 293 in 1928. The progress made by the Propaganda section during the year was good. The Government note with regret that the municipalities of Tenali, Ongole, Palacole and Tiruvannāmalai have been persistently neglecting propaganda work and that the work done in Gudiyāttam, Peddapur, Villupuram and Narsaraopet has been far from satisfactory.

Sanitary works.—During the year no new water-supply scheme was brought into operation. The Vellore drainage scheme was completed and handed over to the municipality, while the Madura drainage scheme was also practically completed except for a few minor works.

During the year, nine water-supply schemes and improvements to four schemes were under execution by the Public Works Department. Besides these, seven other water-supply improvement works were entrusted to municipalities for execution. They were in Periyakulam, Vizagapatam, Vizianagram, Bezvada, Tirupati, Guntūr and Ongole.

The Gōbichettipālaiyam water-supply scheme was sanctioned during the year, while the financing of four schemes (Madura water-works improvements, third stage, Erode drainage, Gudur water-supply and Saidapet water-supply), for which plans and estimates had been prepared, was under the consideration of Government. Besides these, there were 16 water-supply and drainage schemes relating to local bodies (including improvements to certain existing works), for which plans and estimates were under preparation. Investigation of various other schemes with approximate estimates was completed, chief of these being the water-supply schemes of Sembiam, Walajapet, Tiruvallur, Tadpatri, Hospet, Virudhunagar, Dēvakōttai and Cochin and the drainage schemes of Sembiam, Coimbatore, Vizianagram and Vizagapatam.

Three reports on the experiments conducted regarding the filtration of water were submitted to

Government. Very valuable results were obtained from those experiments.

BENGAL PUBLIC HEALTH REPORT FOR THE YEAR 1927. BY DR. C. A. BENTLEY, M.B., D.P.H., D.T.M. & H., CALCUTTA, BENGAL SECRETARIAT BOOK DEPOT, 1929. PRICE RS. 6-10-0.

DR. BENTLEY'S annual reports are always interesting reading, and the present one is no exception to the rule. A special feature of these reports is that they are admirably illustrated by graphs and charts.

Rainfall was in slight defect generally in Bengal in 1927, the year being a rather dry one with a prolonged hot weather. The total population on which the returns are based may be taken as 46,522,293. The central feature of the report is that, notwithstanding higher mortality than usual from cholera and smallpox, the population of Bengal continued to increase, naturally not quite to the same extent as in the previous year. As compared with the previous year the total number of births rose from 1,276,380 to 1,286,863, and the deaths from 1,151,197 to 1,189,370. Allowing for a probable omission of 27 per cent. in the registration of births and deaths, actual birth- and death-rates of the province may be assumed to be 35.17 and 32.51 respectively. A beginning was made in 1927 with the transfer of the responsibility for collecting vital statistics to Union Boards, a function for which provision is made in the Village Self-Government Act, but which they have been on the whole somewhat reluctant to assume.

A number of interesting maps show at a glance the chief points in connection with vital statistics for the province. Taking the natural rate of increase per mille of the population in the different provinces of India, the Punjab heads the list with a figure of 14.8, and Bengal is last with a figure of only 2.1 per mille. Calcutta, Jessore, Howrah, the 24-Perganas, Hooghly, Khulna and Bakarganj all showed an excess of deaths over births. Since 1898 the birth-rate in Bengal has shown a steady decline, but so also has the mortality rate, and this is shown on p. 11 in a striking graph. Six districts only showed an increase in the birth-rate in 1927 over the ten year average, and eleven an increase in the corresponding death-rate. Dinajpur, Rajshahi, and Murshidabad all showed a total mortality of over 30 per mille.

Infant Mortality.—The number of deaths among infants under one year of age was 229,078 as compared with 251,184 during the previous year, the decrease in the reported rate of infantile mortality being 9.6 per cent. As usual more male infants died than female infants. Calcutta and Bakarganj showed an increase in infant mortality over the average of ten years, and on p. 23 is given a very interesting set of graphs showing changes in infant mortality in different districts from 1921 to 1927; Calcutta tops the list with 340 infant deaths per 1,000 births. (This, however, as in all the large cities of India, is to some extent due to the fact that very many Hindu women return to their homes in the *mofussil* for their confinement; the birth is thus recorded in the *mofussil*, but the child's death after its return to the city is recorded in the vital statistics for the city. This error is prevalent in all the records for such cities as Calcutta, Bombay, and Madras, and makes the actual case out worse than it really is.)

With regard to maternity and child-welfare, extremely interesting results have been obtained in Calcutta and Dacca by special attention to midwifery and the care of infant life. In Calcutta there were five units at work staffed by 5 lady health visitors and 18 midwives. In 4,748 cases attended by them the death-rate during the first ten days of infancy was only 35.5 per thousand as against the average for the city of 104.8 per thousand, while only 13 cases proved fatal to the parent. Two maternity centres working in the town of Dacca, and dealing with slightly over a thousand cases, reported a mortality during the first ten days of infancy of only 22 per thousand as against a recorded mortality of 96 per thousand in the rest of the town. These figures

go to show what can be accomplished by the proper care of mothers and infants.

During the year under review grants-in-aid were made to various local bodies for starting 100 classes of 10 *dais* each. In all 1,170 *dais* received training in 104 classes started by 49 local bodies and one health society. Public interest in maternity work and infant welfare was maintained and 67 health exhibitions and Baby Week functions were held during the year.

HISTORY OF THE CHIEF DISEASES.

Cholera.—The year 1927 was a bad one for cholera in Bengal, the epidemic season setting in, however, later in the year than usual. In Malda district 17.9 per cent. of all deaths during the year were due to cholera. The riverine districts are especially affected, and the Darjeeling district hardly at all.

The mortality from cholera was 118,377 in 1927 as compared with 59,106 in 1926, showing an increase of 92.3 per cent. above that year and also above the decennial average. The measures taken to cope with the epidemic included inoculation, disinfection of water-supplies, disinfection of infected houses and of the patients' clothes and supply of bleaching powder. Twenty medical officers and a temporary epidemic staff of 20 Sub-Assistant Surgeons and 100 sanitary inspectors were deputed to help local bodies in suppressing outbreaks. The publicity work carried on by the Publicity Branch of the Public Health Department by means of lectures and magic lantern demonstrations and free distribution of posters and leaflets on the prevention of cholera has gone far to show the public how far cholera may be regarded as a preventable disease. Local bodies concerned kept special watch over pilgrims for the Puri *rathjatra* and the Ganga Sagar *mela* with a view to detecting suspected cases.

The cholera epidemic of the year 1927 gave the first impetus to the mass vaccination for cholera which made such remarkable strides. In 1927 1,299,630 c.es. of cholera vaccine were issued as against 256,000 in 1926, while the number of inoculations reported jumped to 781,872 from 57,395 in the previous year.

Smallpox.—The mortality from smallpox was also distinctly above the average, 42,514 deaths being reported as against 25,548 in the previous year. The epidemic was attended with an increase of over 20 per cent. in activity in vaccination and nearly four million adults and children were vaccinated during the year. More than half of the precise total of 3,975,837 were revaccinations, but the number of primary vaccinations 1,928,674 was well above the total number of births reported. Protection is obviously increasing so long as more persons are vaccinated for the first time than are born in the year, but the actual percentage of successful vaccinations among the infants of 1927 was only 26.1 and slightly less than that of 1926.

Fevers.—The death-rate from "fevers" was 17.0 per mille, as compared with a figure of 17.7 for 1926. A graph on p. 45 shows how the rates vary year by year in the different districts. The chief fever season was from June to November, as usual. Nadia and Burdwan were the only districts to show fever indices from malaria of over 50 per cent.

Of anti-malaria schemes, the result of the Banka Valley scheme was good, flushing being carried out from July to October. In the Singaran-Toposi scheme of the Singaran river, which breeds enormous numbers of *A. culicifacies*, was flushed; here not only has malaria decreased, but with it also the infant mortality. At Mcenglas Tea Estate the spleen index has come down to about 57 per cent. and now appears to be remaining at about that figure. The work of the very numerous anti-malaria societies whose activities now almost cover the province is dealt with on pp. 51 to 53 of the report.

The figure for kala-azar is less than for previous years, and it appears likely that the peak of high incidence of recent years—largely due to better methods of diagnosis, and the increasing popularity of treatment—has been passed. Enteric fever is on the increase in the towns, again possibly because of better diagnostic

methods. Relapsing fever was unimportant, and only one case of plague was reported during the year. Dysentery and diarrhoea showed an increase, associated with the special incidence of cholera during the year; there was also an increase in the number of deaths from respiratory diseases.

Tuberculosis.—The figures suggest that the incidence of pulmonary tuberculosis is gradually rising in Bengal. Kursong reported the highest death-rate from this disease—3.6 per mille, Darjeeling a figure of 3.3, and Calcutta one of 2.5.

Miscellaneous.—The port health activities were carried on as usual in Calcutta and Chittagong, the only events of note being an outbreak of measles on the S.S. *Ganges*, and a mild outbreak of beriberi among the crew of the Chittagong Port Trust vessels.

The Bengal Public Health Laboratory examined 1,933 routine specimens during the year, and carried out a considerable volume of research work on milk, the constants for pure buffalo *ghee*, imported and adulterated *ghee*, and tube well waters. Mustard oil is perhaps more commonly adulterated than any other article of diet among the population in general.

The year surpassed all past records with reference to school hygiene, 196 schools having been inspected. In all 1,170 *dais* received training in 104 classes. The Publicity Officer, Rai Sahib K. P. Ray, did excellent work, whilst the Eastern Bengal Railway demonstration train, which tours the districts giving cinema and other demonstrations, was a great success; no less than 186,000 people visited the demonstration health car. The usual precautions were taken with regard to fairs and melas.

Rural Public Health Organization.—The year 1927 witnessed the beginning on a small scale of a movement which may have far-reaching effects in remodelling public health organization in the districts in future years. This is the system of founding public health circles corresponding in area to a *thana*, to each of which is attached an officer specially trained in public health work. Towards the cost of such centres Government contribute the actual expenses up to Rs. 2,000 for each unit per annum. With the assistance of Public Health Committees for the *thanas* it is not difficult to foresee how such centres may on the one hand facilitate the decentralization of public health work from District Board headquarters, and on the other hand link up the efforts of individual Union Boards for the improvement of public health in the *thana* as a whole. Among other advantages they should ultimately afford a medium for the better control and inspection of vaccination. These new public health circles were first brought into existence in August 1927 and 258 had been established by the end of March 1928.

Public Health Department, Engineering Branch.—In time of financial stringency lump grants for expenditure in the province as a whole are more easily justified than specific provision for works of sanitary engineering for the benefit of one town or another, and for this reason the public health engineer feels the pinch more acutely than the medical and scientific branch of the public health establishment. There were actually in progress, however, in 1927 under the Chief Engineer ten schemes of water-supply and drainage in various stages, while eight other schemes were completed during the year; and the work of preparing further schemes for provision in later years went on so far as there was any practical possibility of their realization.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF ASSAM FOR THE YEAR 1928. BY MAJOR S. L. MITRA, B.Sc., M.B., Ch.B., D.T.M. & H., I.M.S., SHILLONG, ASSAM GOVERNMENT PRESS, 1929. PRICE RS. 2-7-0.

LIEUT.-COL. MURISON, I.M.S., held charge throughout the year, but proceeded on leave before this report was written. After an introduction dealing with general meteorological conditions for the year, the report proceeds to a discussion of vital statistics. These are based on an approximate (pains) population of 6,852,242.

Vital Statistics.—Both the birth-rate and the death-rate improved during the year 1928, and the excess of the former over the latter, which represents the natural increase of the population, was higher than in any year since the reconstitution of the province in 1912. The birth-rate rose from 30.25 per mille in the previous year (and 30.01, the quinquennial average) to 31.24, and the death-rate decreased from 23.47 in the preceding year (and 23.97, the quinquennial average) to 22.16 per mille. Only in two other provinces, namely, Burma and the North-West Frontier Province, was a lower death-rate recorded. The Director of Public Health attributes these satisfactory features, which, despite the dubiety of such comparisons owing to defects in registration, are reflected in the statistics of mortality from all the principal diseases except smallpox, to better health conditions following the favourable climatic factors of the year and to prosecution of the intensive campaigns against cholera and kala-azar.

The death-rate on the tea estates, 18.01 per mille, was again considerably lower than the provincial rate. This is evidently due to the better sanitary conditions and supervision prevailing on the tea estates; and, though the proportion of births is still lower than that in the province as a whole, the increase in the garden population was 10.1 per mille or 1.03 more than the provincial increase. The health of the larger towns was also satisfactory, save in Shillong, where the problems of sanitation have caused Government some concern.

There was no change in the agency employed for the collection and registration of vital statistics. Since, as was pointed out in the resolution on the last annual report, the value for statistical purposes of the registration returns depends upon the accuracy of the collection, it is regrettable that there was also little improvement in the work of the agency responsible. Birth-rates in the rural areas range between 56.79 and 3.67 and death-rates between 43.61 and 3.50, figures only too indicative of defects. The percentage of omissions found by the vaccination staff in checking urban registration was considerably higher for both births and deaths than last year, and it is clear, as the Director of Public Health points out, that more attention must be paid to this check particularly in the smaller towns and also in Sibsagar and Golaghat. Though registration is compulsory in the towns, no less than three important towns, including Shillong, appear to have made no check at all.

Infant Mortality.—Infant mortality in Assam is still at the high figure of 172 deaths per mille of live births, but this compared favourably with such provinces as the Central Provinces, where the figure is 238, and Burma with a figure of 209. The figure for Assam has very slowly declined from 197 in 1912 to its present level.

History of the Chief Diseases.—Influenza was unimportant during the year. Cholera was less important than in the epidemic year of 1927. The covering Government resolution to the report on this reads as follows:—

Government observe with satisfaction the decrease in the number of deaths from cholera reported during the year, which were 6,915 as compared with 15,392 in 1927. A temporary epidemic unit was created for the district of Goalpara, which had lightly escaped in 1927 but showed the highest death-rate from cholera, i.e., 2.30, in 1928. The epidemic staff in Sylhet, which district reported the next highest death-rate, was increased by two more units consisting of six sub-assistant surgeons and twelve disinfectant carriers. The epidemic units appear to have fully justified their existence, though the system of co-ordination enabled the assistant and the sub-assistant surgeons of the kala-azar staff, the sub-assistant surgeons of the local board dispensaries and the subdivisional medical officers also to play their part. The units were employed, in addition to the actual treatment of patients, on the disinfection of water-supplies, inoculation of all possible contacts with anti-cholera vaccine, and the instruction of the people in the dangers arising from impure water by magic lantern slides and other means. It has been

mentioned that the figures show people to be taking more freely to inoculation. The manufacture of cholera vaccine at the provincial Pasteur Institute has been satisfactory in enabling prompt supplies to be made. An important step has been taken in the manufacture of combined cholera and dysentery bacteriophage at the Pasteur Institute and its administration both as a prophylactic and as a remedy in selected areas. The method as applied to epidemics is still in an experimental stage, but the results are remarkably encouraging. The problem of manufacturing a uniform product is nearing solution. That, however, of securing proper controls in the field is, Government understand, the chief difficulty in the experiment. A demonstration of the value of this product as a simple and readily available tool in epidemics of cholera and dysentery would be of more than provincial importance.

Smallpox was severe during the year; a total of 8,461 deaths as compared with 5,237 in the previous year. It was especially prevalent in Sylhet, Cachar, and Goalpara.

The total number of deaths registered from smallpox during the year under report was 8,461 as compared with 5,237 in the preceding year. The death-rates for the two years were 1.23 and 0.76 respectively, as compared with 0.42, the average of the previous ten years. The increase in mortality from smallpox, particularly in Sylhet, is, according to the Director of Public Health, mainly due to defective vaccination and slackness in supervision of the work of the vaccinators. Though the vaccinating staff has recently been increased, he has called attention to a more serious defect than shortage of staff in the absence of efficient control. The provision of an adequate supervising staff of rural health officers as adumbrated in the resolution on the last report may not be possible in the early future. Meanwhile Government have under consideration the possibility of improving the means of control, so far as the fault lies with the rules and orders and with division of responsibility between the Civil Surgeons and the local boards.

The report for 1928 includes for the first time a chapter corresponding with the triennial report hitherto separately published on vaccination, and the Director has therefore included the vaccination figures for the past three years. In future only annual figures will be required. The results are interesting, and the Governor and his Minister are glad to observe that they indicate a growing popularity of vaccination among the masses. This may in part be due to the advantages attending the use of anti-cholera vaccine and the phenomenal success of kala-azar injections.

*Fever*s accounted for a mortality of 13.03 per mille, a relatively low figure. The deaths from this cause have dropped from 1,13,098 in 1924 to 89,255 in 1928. Nazira and Doom Dooma reported high fever incidence, but as there are no medical officers of health in either town, this may be due to inaccurate reporting by village chowkidars. Deaths from kala-azar in Assam increased from 1,667 in 1919 to 6,365 in 1925, and then decreased to 1,660 in 1928. Cases treated rose from 7,118 in 1920 to 60,940 in 1925, and have thereafter declined to 23,576 in 1928. In other words, the strenuous efforts of the kala-azar survey staff in Assam are now bearing fruit, and the disease is steadily being brought under control. The North Cachar Hills require re-survey.

Anti-malaria measures were continued at Pasighat, Haflong, Kohima and Lumding and were undertaken in the forest area at Kachugaon in the Goalpara district. Malaria is, however, of such widespread importance in Assam that these measures hardly touch the fringe of the problem. As quinine treatment must always form a prime factor in dealing with this disease, the Governor and his Minister are glad to hear that the number of parcels of quinine sold during the year rose to 7,841 from 5,570 in 1927. They hope, however, that the time may not be long delayed when it will be possible to organize a campaign against the root causes of malaria, which continues to be a constant cause not only of sickness and death but also in all probability of lowered vitality.

The campaign against kala-azar was continued with vigour as in preceding years. The number of deaths from kala-azar fell from 2,859 in 1927 to 1,660 in 1928, and the number of cases from 33,415 to 23,576 in the two years. This satisfactory result, as the Director remarks, is due to the continuance of free treatment with urea stibamine throughout the province. The Governor and his Minister have read with pleasure the account of the good work done by the special staff, and of the co-operation of the Civil Surgeons and their subordinates. They fully recognize the difficulties met with by the staff engaged in such a campaign, especially in a primitive and rugged area like the Garo Hills, and regard it as therefore all the more important that the staff should be carefully selected for the purpose, and hill men utilized as far as possible for work among the hill tribes.

It is observed that there is a satisfactory increase in the expenditure of local bodies upon conservancy, but that the amount spent upon drainage is still lamentably small. Proper drainage constitutes an important health factor, especially in malarious places. It is hoped that a Public Health Engineer will shortly be appointed and that the Director will in the future find less matter for adverse comment in the sanitation of the towns.

Dysentery and diarrhoea accounted for a death-rate of 1.24 per mille, whilst the incidence in tea estates was reported to be lower than in the previous year. Plague was absent.

"The Governor and his Minister" have perused with interest the remarks of the Director concludes the covering Government resolution, anent the prevalence of food adulteration. They are at present in doubt whether the Public Health scheme mentioned by him in view of the recent floods will be financially possible in the immediate future. His opinion that there is need for a provincial Food Adulteration Act engages attention. It is, however, a question requiring close consideration whether the existing provisions of law are not adequate in view of the present limitations of staff and popular education, and in particular whether the provincial laboratory as at present constituted would be capable of operating such an Act.

REPORT OF THE HEALTH OFFICER OF CALCUTTA FOR THE YEAR 1927. BY DR. T. N. MAJUMDAR, D.P.H., D.T.M., F.C.S. (Lond.), F.R.S.E., CALCUTTA CORPORATION PRESS, 1929.

This report is very well documented and illustrated. Owing to the addition of the municipalities of Cossipore-Chitpore, Manicktolla, and Garden Reach to Calcutta city by the Calcutta Municipal Act of 1923, three sets of vital statistics are given in order that comparison may be made with former years. Greater Calcutta now covers an area of 30½ square miles, with a population of 1,077,264. The death-rate in 1927 was 34.1 per mille, calculated on the census population of 1921. As usual Entally, Beniapukur, and Tollygunge showed the highest mortalities, in all instances over 50 per mille. Entally indeed recorded a figure of 70.5, largely due to dysentery. The death-rate is much higher for females than for males, is highest among the Mahomedan community, and lowest among Europeans. March was the month of highest incidence, largely due to epidemic disease.

Infantile mortality was 339.7 per mille. The highest infant mortality occurs in the urban wards with their overcrowded buildings and congested areas. Bronchitis and broncho-pneumonia are given as the principal cause, and tetanus neonatorum accounted for 12 per cent. of the deaths. Syphilis is extremely rife and accounts for most of the premature births. A striking feature in the infant mortality is that diarrhoea and enteritis account for only 6 per cent. of the deaths; this is due to the almost universal custom of breast feeding. Infant mortality was highest in the Mahomedan community—434 per mille, and lowest in non-Asiatics and Anglo-Indians.

The birth-rate was only 15.5 per thousand of the population. Owing to the peculiar composition of the population of Calcutta, however, which contains twice as many males as females, this figure has but very little meaning. The birth-rate, as calculated on the number of women of child-bearing age, was 142 per mille. Fertility is highest among the Hindu community, and lowest among the Indian Christians.

PRINCIPAL DISEASES.

Cholera was more prevalent than usual, incidence 1.8 per mille. If the added areas be included, the figure is 2 per mille. The epidemic of 1927 followed the usual normal distribution, reaching its height in April. The riparian wards and those abutting on Tolly's Nullah were chiefly affected, as usual. The principal causes are bathing in the Hooghli and Tolly's Nullah, the use of the unfiltered water-supply for domestic purposes, contamination of food-stuffs by carriers, and flies. The seven principal bathing festivals of the year are invariably accompanied by an increase in the cholera mortality. Cases are also constantly being imported into the city and help to spread the disease. Eighty-seven per cent. of the cholera mortality occurs among the Hindu community, and mortality is highest among young children and aged persons.

Smallpox.—The epidemic of 1927 was severe, the total mortality being 2,860 deaths or 2.6 per mille. There have been 8 epidemics of smallpox in Calcutta during the past 30 years—an ominous record. The epidemic began, as usual, in December of the previous year, and reached its height in March (1,008 deaths); it was practically over by July. Entally, Beniapur, and Manicktola—the plague spots of Calcutta—again headed the mortality list. The incidence was 2.9 per mille amongst Hindus, and 1.6 per mille amongst Mahomedans; deaths among females were twice those among males. Dr. Majumdar is rightly emphatic about the necessity for making re-vaccination compulsory. One-third of the deaths from smallpox occurred amongst infants and children.

Measles was epidemic during the year, especially in the spring. Deaths numbered 108 or 0.11 per mille. Hindu infants and children were chiefly affected, and females more than males. **Enteric fever**, mortality 0.78 per mille in 1927, is always endemic in Calcutta, being prevalent in two periods, during the spring and in the autumn. The "treatment" of such patients in their own homes instead of in an infectious diseases hospital materially helps in spreading the disease. Hindus are affected much more than Mahomedans.

Malaria, with a death-rate of only 1.1 per mille, is unimportant in the city proper, but is prevalent in the environs. Garden Reach, for example, recorded a figure of 3.9 per mille, followed by Beniapur and Entally, both with 3.8. A "black list" is given of wards with numerous tanks, *kutcha* drains, and low-lying undrained areas. The maximum incidence is in December, but there has been an appreciable reduction in the incidence of the disease of recent years. The disease is three times as prevalent among Mahomedans as amongst Hindus, and the former community appears to be especially susceptible. "Other fevers" gave a general mortality rate of 1.9 per mille.

Dysentery and diarrhoea are very prominent in the returns, with a figure of 3.5 per mille. These diseases are most prevalent in the cold weather, December being the month of maximum incidence. Tollygunge, Garden Reach, Satpukur, and Entally were the wards chiefly affected. The highest mortality rates occur at the extremes of life, and females are more affected than males. Even with a protected water-supply these diseases constitute a serious problem in Calcutta.

Tuberculosis is apparently on the up grade in Calcutta, the figure for incidence having risen steadily from 2.4 per mille in 1921 to 2.7 in 1927. There is little seasonal variation, and almost the whole mortality is due to pulmonary tuberculosis. The root causes are poverty, indiscriminate expectoration, bad housing, and the purdah system. Mahomedans suffer more severely than

Hindus, and the saddest feature of all is the terrible incidence amongst Mahomedan purdah women of child-bearing age. An Anti-Tuberculosis Society has recently been started in Calcutta, but nothing short of re-building large areas in northern and central Calcutta will really eliminate the scourge.

Respiratory diseases (other than pulmonary tuberculosis) accounted for a mortality of 6.7 per mille. The highest mortality from these occurs during the cold weather, and especially affects the suburban wards which are badly drained and subject to flooding. Acute bronchitis is the chief cause of death among infants, and chronic bronchitis is especially prevalent among the aged. Females are affected more than twice as frequently as males. Influenza, as usual, was endemic.

Kala-azar showed a diminution, mortality 0.54 per mille. From 1917, when better methods of diagnosis and treatment were first introduced, the mortality in Calcutta from this disease increased at a tremendous rate, till it reached a peak in 1925. (This was due rather to better diagnosis and the influx of patients from the *mofussil* for the new methods of treatment at the Calcutta hospitals, than to any real epidemic spread of the disease. The years 1926 and 1927, however, showed a reduction. It is only in the more central wards of the city that the disease is endemic and is spreading, since in northern Calcutta *Phlebotomus argentipes* has every opportunity for feeding on the cow rather than on man.) The incidence of the disease in Calcutta falls with special severity on the Indian Christian and Mahomedan communities.

MISCELLANEOUS.

Pages 20 to 22 of the report deal with the work of the sanitary officers, and record a total of 5,199 improvement projects carried out. The total fines realized as the result of prosecutions for insanitary practices shows an appreciable rise on the figure for 1926, Rs. 60,068 as against Rs. 53,127, but the majority of offenders are simply dismissed by the magistrates with a warning—a most unsatisfactory state of affairs. Much more and much better accommodation is urgently needed for dhobi-khanas for laundry work.

A total number of 5,245 miscellaneous samples of food-stuffs was collected and examined; no less than 1,174 were found to be adulterated, or 22.3 per cent. Mustard oil especially is liable to adulteration, whilst "milk" may be anything. The work of the Co-operative Milk Societies' Union, however, deserves honourable mention. The ice and soda water factories in general were in a satisfactory condition, and are systematically inspected.

The work of the sixteen free dispensaries under the control of the Corporation was carried on as usual, whilst twenty-eight ward health associations were at work. Seven maternity centres were also working, and did much admirable work. No less than 5,280 confinements were attended to by the trained staff at these centres; the maternal mortality in these cases was only 2.2 per thousand deliveries, and the infantile mortality only 23.2 during the first ten days following birth; figures which show how immensely important this work is in Indian cities.

The number of vaccinations, 2,32,256 was greatly in excess of the figure for 1926—largely as the result of the smallpox epidemic. A very severe strain was put on the Vaccine Lymph Depot by the epidemic, and more than one and a half lakhs of tubes of glycerinated lymph were issued. Other issues were also made to medical practitioners, chemists, and to areas outside Calcutta. The success rates in different wards for primary vaccination ranged from 95.4 to 99.3 per cent., and the results are exceedingly good.

The Corporation Laboratory was in charge of Dr. T. K. Ghosh, B.A., L.M.S., F.C.S. A total of 17,170 specimens was examined, whilst the Milk Laboratory at the New Market continued its daily analysis, both morning and evening, of the milk supplies. The water-supply is tested daily; for some reason the filtered supply when

it reaches the city is less satisfactory than when it leaves the settling tanks at Pulta and Tallah; this is probably due to leakages in the distribution pipes. The "underground" problem in Calcutta indeed is rather a serious one, for main sewers and main water-supply pipes run close together—sometimes in the same bed—and three instances of contamination from this cause are given in an appendix to the report. The pressure inside the water mains is low, and the filtered water-supply is often very defective in some areas in the city, especially during the hot weather, and with water mains alongside main sewers—and in some instances actually crossing the interior of the sewer—the chances of contamination are very great. The only remedy, short of relaying the system, would be to maintain a sufficient head of pressure in the water mains to keep contamination outside. Further, underground masonry reservoirs are apt to be very unsatisfactory; they are difficult to clean and liable to cracks and fissures. A very bad example of this recently occurred at no less a place than the Calcutta School of Tropical Medicine and Hygiene, where it was found that an underground reservoir there, constructed by a contractor to the Public Works Department, was faulty and its water badly contaminated. Dr. Majumdar is of the opinion that all underground reservoirs should gradually be closed down, and their place be taken by overground tanks of galvanized iron.

The usual appendices close the report. Dr. Majumdar is to be congratulated on a year of very hard work and a most interesting report. Public health problems in Calcutta city are extremely difficult ones, and it needs an officer of both courage and ability to tackle them.

Correspondence.

UNDESCENDED TESTIS AS A CAUSE OF PHYSICAL REJECTION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In the October number of the *Gazette* under the above caption Dr. Rameshwar Singh, Civil Surgeon of Muttra, writes a letter and wishes to know what the risks of this condition are, and if such cases should be rejected for enlistment or not. He also mentions that he rejected a recruit because he did not like the risk of a strangulated hernia.

Now it is presumed on his own statement that the type of case he had was of the abdominal type; and in such cases there is no fear of strangulation occurring. They are the least harmful or objectionable, but in advanced years become the seat of malignant degeneration.

The other two varieties of undescended testis are:—

(a) Femoral. (b) Inguinal.

The former (a) is most troublesome, imparts an uncomfortable feeling to the patient, often amounting to pain, and is liable to injuries from various causes too obvious to mention, and in which torsion of the cord may at any time occur, giving rise to alarming symptoms, and calling for urgent interference. The latter (b) is the most common variety and the most liable to strangulation and to the development of a strangulated hernia, due to the patency of the canal.

In the case of (a) and (b) operation is advisable to avoid the complications noted above, and also to render the patient physically fit.

In the case of the abdominal type, the question is problematical as the only complication or danger is the liability to malignant degeneration in later life.—Yours, etc.,

A. BAYLEY-DE-CASTRO,
LIEUT., I.M.D.,

HYDERABAD, SIND,
28th November, 1929.

"NAGA" SORE IN RAJPUTANA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In your issue for December 1928 there was an article by Dr. D. N. Roy, M.B., D.T.M. (Bengal), on "Naga" sore.

In August last when I returned from leave I saw many cases of peculiar ulcers in the out-patient department here, and on enquiry was told that such cases had become very common within the previous few days. I referred to Dr. Roy's article and found that these cases corresponded exactly with his description of "Naga" sore. At the time they were present here in epidemic form.

I commenced to examine the cases, and from a study of some one hundred and fifty, came to the following conclusions:—

(i) In the majority of cases the first lesions were a slight itching or scratch or some trauma. In some instances the ulcers were due to guinea-worm infection.

(ii) The ulcers were always on the leg, ankle, or foot only.

(iii) The ulcer was generally circular, its edges undermined, and its margins raised. There was a foul, purulent, tenacious slough. Lymphangitis was noticed only around the ulcer. In some cases there was a sero-sanguineous discharge from the ulcer. If left untreated, the ulcer steadily deepened and eroded more and more tissue.

(iv) On microscopical examination of the direct smears of the discharge, also of smears from the margin, the slough, and the ulcers after scraping, fusiform bacilli, spirochaetes, and diplococci were seen. The majority of cases gave positive results, though some were negative.

(v) The incidence of the disease lessened by the middle of October, though occasional cases still continued to crop up.

(vi) Some of the patients had more than one ulcer.

(vii) The ulcers were commonest among poor people and young schoolboys.

(viii) Anti-syphilitic treatment was of no avail in these cases.

(ix) I followed Dr. Hugh Smith's method of treatment, and all my cases did very well.

This experience shows that such ulcers are common, not only in Assam, but also in other parts of India, where they have escaped notice perhaps. These ulcers appear to constitute a definite clinical disease entity, and research work in connection with them is very necessary.—Yours, etc.,

MALUM SINGH B. DOSHI, M.B., B.S., B.Sc.,
Chief Medical Officer.

DUNGARPUR, RAJPUTANA,
6th November, 1929.

(Note.—Dr. Doshi's letter raises most interesting and important problems. *Ulcus tropicum* is at present a rather badly defined entity. In the case of "Naga" sore, what is present is apparently Vincent's infection; in the case of Veldt sore of South Africa, however, and in cases described by Craig during the war from the Sinai desert, the infection present was one with diphtheroid bacilli, possibly cases of true cutaneous diphtheria. The writer remembers having seen cases exactly similar to those described by Dr. Doshi in Jhansi in the United Provinces in the monsoon periods of 1909–1911; they were especially prevalent among grass cutters attached to cavalry regiments.

The special tendency of these sores to occur only below the tubercle of the tibia suggests that the primary lesion is always of the nature of an abrasion, the *ulcus tropicum* infection being superimposed on this. We agree with our correspondent that the whole subject badly wants investigation.—Ed., I. M. G.)

THE AGE OF CONSENT ACT.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—You have done nothing more than your duty in opening the columns of the *Indian Medical Gazette* for expression of authoritative opinion on this subject.

First of all, let me deal with religion and dogma. What atrocities have not been perpetuated all over the

world in the holy name of religion, and when has not the sanction of the scriptures been invoked, when intelligent enquiry, fairness, and equity have dictated a line of conduct and action opposed to the interests of the selfish priesthood? I claim to be as good and earnest a Hindu as anyone, and I firmly declare, first that the Hindu religion not only does not sanction early marriage, but forbids it; and, in the second place, should anyone ransack the vast Sanskrit literature to produce evidence to the contrary, I boldly assert that such "scriptures" as a Hindu have no meaning for me. Can anyone say that a man is not a good and pious Christian because he does not believe that the "sun, the moon and all the stars" were created on the sixth day?

Undoubtedly marriage is a sacrament, but early marriage goes against all the established laws of physiology. The origin of early marriage in India dates back to the time when the country, owing to foreign invasions and internecine quarrels, became unsafe and virgins were considered a lawful prey by the invaders. In ancient India no one ever thought of marrying a girl of fourteen. Do we not read how maids chose their husbands in overt assemblies of men? Bengal, the United Provinces, and Bihar were most subject to invasion and unsettled government, and in these provinces purdah and early marriage became a custom in the near past.

Early marriage prevents the girls from being properly educated. When subjected to ill-treatment child wives are incapable of self-defence. Their husbands being usually without independent means, they are generally neglected, and consequently eclampsia and sepsis—as mentioned by Col. Green-Armytage—are rampant among girl mothers. Early parenthood leads to ill-formed offspring, who, being still further unprovided for, increase the family burden of the father, who is still at school.

Interested parties will continue to raise objections, and some men, otherwise known to be calm and sedate, are liable to be taken in. Some others would raise a storm in order to come into the limelight themselves. When *suttee* was suppressed by Cornwallis, was not a storm of protest raised, and the cry made that Hinduism was in danger? But *suttee* is now no more, and Hinduism still survives. The same will be the case with this futile and puerile protest against an eminently beneficial and beneficent measure such as the Age of Consent Act.—Yours, etc.,

SHIAM MANOHOR LAL, RAI BAHADUR,
Civil Surgeon.

JHANSI,
20th November, 1929.

Service Notes.

APPOINTMENTS AND TRANSFERS.

THE undermentioned officer is appointed Honorary Physician to the King with the Brevet rank of Colonel:—Lieut.-Col. E. C. Hodgson, D.S.O., I.M.S., *vice* Major-General Sir W. H. Ogilvie, K.B.E., C.B., C.M.G., M.B., I.M.S., from the 2nd September, 1929.

Lieut.-Col. J. L. Lunham, M.B., F.R.C.S.I., I.M.S., is appointed to officiate as Surgeon-General with the Government of Bombay, with effect from the date he assumes charge and until further orders.

Major H. J. H. Symons, M.C., I.M.S., an Agency Surgeon, on return from leave, is posted as Residency Surgeon, and ex-officio Vice-Consul, Bushire, with effect from the 8th November, 1929.

On relief by Lieut.-Col. M. S. Irani, I.M.S., Lieut.-Col. A. G. Tresidder, C.I.E., M.D. (Lond.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S., to officiate as Civil Surgeon, Karachi.

The services of Major A. H. Shaikh, I.M.S., are placed permanently at the disposal of the Government of the United Provinces for employment in the Jail Department, with effect from the 1st October, 1927.

Major H. K. Rowntree, M.C., I.M.S., Civil Surgeon, Simla East, is appointed to hold charge of the duties of the Civil Surgeon, Simla West, in addition to his own, during the absence on leave of Lieut.-Col. N. M. Wilson, I.M.S.

The Governor in Council is pleased to confirm Major E. E. Doyle, D.S.O., I.M.S., in his appointment of Inspector-General of Prisons, Bombay Presidency, with effect from the 14th September, 1929, *vice* Lieut.-Col. J. H. Murray, C.I.E., M.D., I.M.S., retired.

Captain T. H. Thomas, I.M.S., on return from leave, is appointed as the First Resident Surgeon, Presidency General Hospital, Calcutta, with effect from the 1st November, 1929.

To be Captains (on probation).

Captain Robert Lewis Frost, 6th August, 1929, with seniority from 15th August, 1926.

Captain Keith Simpson Fitch, 6th August, 1929, with seniority from 13th April, 1927.

To be Lieutenants (on probation).

William McAdam, M.B., 6th August, 1929, with seniority from 6th August, 1928.

William McCoach, B.Sc., M.B., D.P.H., 30th August, 1929, with seniority from 30th August, 1928.

Gerald Gerard Mark Davis, M.B., 6th August, 1929.

Daniel Hyacinth Waldron, M.B., 6th August, 1929.

Edmund Patrick Noel Mary Early, B.A., M.B., 6th August, 1929.

Edward Barton Eedle, M.B., 27th August, 1929.

LEAVE.

Lieut.-Col. A. N. Dickson, I.M.S., an Agency Surgeon, is granted leave on average pay for 8 months under Fundamental Rules, with effect from the 8th November, 1929.

Lieut.-Col. F. Stevenson, I.M.S., an Agency Surgeon, is granted leave on average pay for 5 months under Fundamental Rules, with effect from the 1st November, 1929.

Lieut.-Col. I. D. Jones, I.M.S., Civil Surgeon, Karachi, is granted leave on average pay for 3 months from 13th August, 1929.

Lieut.-Col. C. R. O'Brien, I.M.S., Civil Surgeon, Dacca, is granted leave for 12 months, with effect from the 17th November, 1929, or any subsequent date on which he may avail himself of it.

In supersession of Education, Health and Lands Department Notification No. 2016-H., dated the 15th October, 1929, Lieut.-Col. N. M. Wilson, O.B.E., I.M.S., Civil Surgeon, Simla West, is granted leave on average pay for 3 months and 23 days, with effect from the 6th November, 1929, and his services are replaced at the disposal of the Government of the Punjab from the 1st March, 1930.

Major R. H. Candy, I.M.S., is granted leave on average pay for 8 months, with effect from 14th February, 1930.

PROMOTIONS.

Lieutenant-Colonel to be Colonel.

Brevet-Col. Ernest Alexander Walker, M.B., F.R.C.S.E. Dated 2nd September, 1929.

Captains to be Majors.

S. N. Hayes, F.R.C.S. Dated 9th September, 1929.

The promotion of the undermentioned officers to the rank of Major is antedated to the dates noted against their names:—

J. C. Chukerbuti, M.B. Dated 17th August, 1927.

N. J. Gai. Dated 20th June, 1926.

J. M. R. Hennessy. Dated 21st July, 1925.

Lieutenant to be Captain.

Donald Page Lambert. Dated 15th October, 1929.

Lieutenants to be Captains (Provisional).

J. F. O. Bodman. Dated 27th September, 1929.

B. N. Hajra. Dated 10th November, 1929.

RETIREMENTS.

The undermentioned officer is permitted to retire from the service, subject to His Majesty's approval:—

Major-General R. W. Anthony, C.I.E., M.B., F.R.C.S.E., I.M.S. Dated 5th November, 1929.

long time, there is no sign of any local inflammation. We have found the same fungus microscopically in cases of intertrigo between the toes and paronychia, see Plate II, fig. 4. Whether it is the same fungus that gives rise to all these different conditions remains to be proved by us.

The causation of these lesions.—For the last three years, as opportunities have arisen, we examined the first seventeen cases of this disease thoroughly by making cultures on various media and using numerous inseminations of the scales on each medium. We were able to grow a black *Aspergillus* in 12 of these cases, and a green coloured one in three cases, giving a result of 15 positive cultures for *Aspergillus* in 17 cases. At that time, we suspected that this *Aspergillus* was the cause of the lesion, owing to the black colour around the sides of the pits.

In scrapings taken from the side of these pits and cleared by 40 per cent. caustic potash, we were unable to find any hyphæ of the *Aspergillus* fungus. This was rather a blow against the *Aspergillus* theory; so we thought we would be able to prove it by studying the keratolytic action of the fungus on the epidermis of the heel. From post-mortem material the skin of the heel was first sterilised by alcohol, etc., then removed aseptically, placed on plaster of Paris platforms kept moist by water in a sterile Petri dish, and inseminated with this *Aspergillus*. The *Aspergillus* colony spread all over the skin of the heel without liquefying the epidermis. So we had to abandon this view. Later on we found that if we attempted to make cultures after allowing these patients to walk from the hospital to our laboratory, we invariably grew *Aspergilli* from their feet, as this fungus is always present in the dust of floors, etc., during the monsoon months. Last year, we realised the danger of using the caustic potash method for studying any fungi invading the glabrous skin, as it always destroys the more friable fungi like the *Malasszia*, *Actinomyces*, etc., besides producing numerous artifacts, which simulate hyphæ. We therefore no longer use it for this purpose of study. The junior author found that by using a modification of Ponder's stain by increasing the strength of the toluidin blue from 0.02 per cent. to 1 per cent. and dissolving it in 2 c.c. glacial acetic acid, 4 c.c. absolute alcohol and 93 c.c. of water, the thick bits of epidermis could be cleared in glycerine afterwards. The fungi were stained at once without any damage to the hyphæ, and the glycerine cleared the epithelial scales so that one could see through fairly thick pieces of tissue. The specimen can be examined in the wet stage with or without glycerine, a coverslip being put on if the slide has to be examined by the high power lens. These cases were studied after staining by McGuire's method, using the one-twelfth objective, and in all the eight cases recently seen we were able to find fine segmented hyphæ of an actinomycotic fungus in the scales. This method has enabled us to study more exactly these fungi

as they grow in the glabrous skin as well as in cultures, and it should be the method of choice in all work on fungi invading the glabrous skin.

The mycology of the fungus.—Microscopically when stained by McGuire's method the fungus is seen in the scales as very fine segmented hyphæ; these are apt to break up into individual segments, at first sight resembling bacteria, see Plate I, fig. 2. This mistake is easily rectified as the individual segments are short stout forms almost as broad as they are long. In cultures, the hyphæ are seen as a non-segmented branching mycelium, the ends of the hyphæ carrying numerous slightly stained oval conidia; see Plate I, fig. 3. In the ordinary stained specimen, i.e., fixation by heat, and staining with Manson's methylene blue, conidia are not usually found, and the mycelium consists of a network of non-segmented branching hyphæ.

These morphological appearances in cultures are exactly similar to the type culture we possess of *Actinomyces bovis* from the American Type Culture Collection.

Cultivation.—Out of the last eight microscopically positive cases, we have been able to cultivate an actinomycotic fungus twice. The reason of our failure has been due to the growth of certain spore-forming bacilli and an *Aspergillus* fungus. Certain precautions must be taken and the patient's foot should be thoroughly scrubbed with soap and warm water, and then washed well with sterile saline, in order to get rid of all extraneous dirt from the feet. The cultures should be made before the patient leaves his bed, after scrubbing his feet. The edges of the pit are first scraped with a fine sharp scalpel, in order to remove the black stain of the wall. Small pieces are then dug out after washing thoroughly in sterile saline and planted on whey agar medium, i.e., a medium which the senior author has used since 1906 and of the following composition, whey, 2 per cent. agar, 1 per cent. peptone, 0.2 per cent. urea and 4 per cent. saccharose. About 50 inseminations are required as any contamination prevents the growth of the fungus, for the growth is very slow, about 10–15 days must elapse before visible colonies appear on the surface of the media.

The fungus grows best under aerobic conditions, and at blood heat, 37.5°C. Within 3 to 4 days on secondary cultures visible colonies appear on the different media. The characters of the colonies on different media are as follows:—

In ordinary peptone broth, a flocculent white precipitate forms which falls to the bottom.

In peptone water, puff ball white colonies grow at the bottom and sides, the few surface colonies kept up by capillary attraction are red in colour, Plate I, fig. 4, No. 6.

Sabouraud's media, black or red limpet shaped colonies on the surface with deep roots into the media, Plate I, fig. 4, Nos. 1 and 2.

Fig. 2.—Objective 1/12th, ocular 10. Scrapings of the scales from the sides of the pits, and stained by McGuire's method. Note the segmented and non-segmented hyphae. The segmented hyphae look rather like chains of bacteria.

Fig. 3.—Objective 1/12th, ocular 10. Culture stained by McGuire's method. Note the non-segmented hyphae and the numerous lighter stained conidia.

Fig. 1.—The appearance of the lesion known as keratolysis plantare sulcatum. Note the pit-like depression with darker staining of the sides.

Fig. 4.—The cultural appearances on the different media. Nos. 1 and 2 Sabouraud's test media; note red and black limpet-shaped growths. Nos. 3 and 4 on whey agar, similar appearance, but more profuse growth. No. 5 coagulated serum. Note degree of liquefaction. No. 6 on peptone water. The colonies at the bottom form white puff balls and the surface colonies red. No. 7 on blood

Whey agar, red or black limpet shaped surface growth with deep roots, see Plate I, fig. 4, Nos. 3 and 4.

Ordinary agar, limpet shaped surface growth with deep roots black or red.

Coagulated serum.—Marked pit-like liquefaction with a small black growth at the bottom of the pit, see Plate I, fig. 4, No. 5.

Blood agar.—Black limpet shaped surface colony, with a small clear haemolysed zone round the colonies, Plate I, fig. 4, No. 7.

The cultural characters are exactly similar to the red and black fungi which we have obtained from cases of mycetoma of the foot (Madura foot).

The value of colour as a character to identify the species of these fungi.

We have been taught that in the clinical differentiation of these fungi, mycetomas may be classified according to the colour of their granules or growths, i.e., black, red and white, whilst the actinomyces have yellow or white granules, and very rarely red ones. Now it is obvious that there are no such colours as black or white. The former only indicates the depth of the primary colours, thus a deep red which may be so deep that it is visualised as black, and when less deep as a red, whilst when no pigment is produced the growth is achromatic or white. There are three primary colours, red, yellow, blue, and the mixtures of these give the various secondary colours, viz., orange, green, violet. So that colour value of the fungi as a differentiating character of a species can only be of value when primary colours are seen, i.e., red, yellow and blue. Thus we can have a red Mycetoma, or a yellow Actinomyces as a colour character of value to identify species. Black and white only indicate when the conditions for pigment production are favourable or totally unsuitable; compare the growth on blood agar and on peptone water, see Plate I, fig. 4, Nos. 6 and 7. The yellow colour of the agar combines with a light red to produce orange or lemon colours, as these are secondary colours. Blue with yellow produces green as is seen during the growth of the *Pseudomonas pyocyaneus*. As far as we know at present, about the genus *Actinomyces* we can only differentiate those colour values that are sufficiently characteristic to enable us to identify a species, viz.:—

(a) Those fungi that are white in colour and never produce pigment on any media used in the cultivation of these fungi.

(b) Those that are red or black in colour, in one or more of these media.

(c) Those that are yellow to lemon in colour, in one or more of these media.

When the depth of the red or blue passes into the invisible end of the visual spectrum of light, the colour must be black. As far as we know no pathological Actinomyces produces a blue pigment. Secondary colours such as orange, lemon are of no value in differentiating species.

Differential diagnosis.

This has been simplified by our clinical description of these lesions, and we can confirm the diagnosis by microscopical examinations by using McGuire's stain, when the fungi can be seen in the scales. In cases of hyperkeratosis no fungi are found, and the nuclei of the horny cells are large, stain well, and have a granular appearance.

In keratolysis plantare sulcatum, the lesions are seen commonly on the thick skin of the tread of the feet, forming pits or furrows with darker sides and are due to a lysis of the horny cells. The lesions are rare on the hands. There is no localised or generalised hyperkeratosis, whilst scrapings made from the sides and stained by McGuire's method show segmented hyphae forming the mycelium. The lesions appear during the monsoon months and disappear in the winter. There is no evidence that syphilis or yaws is a causative factor.

There are various hyperkeratoses, localised or generalised, of the palms and soles that have been mistaken for this lesion.

(1) Symmetrical hyperkeratosis of the palms and soles, known also as tylosis or mal de Meleda. The hyperkeratosis involves the whole palm and sole with immense thickening of the horny layer, and accentuating most of the furrows on the hand, so that the hands and feet cannot be extended fully, see Plate III, fig. 1.

(2) Keratoderma of the hands or feet with moderate hyperkeratosis and deep fissuring. Most of these cases are associated with special occupations; thus cultivators have lesions on the feet, i.e., cracked heels; and betel sellers, etc., on the palms. Some of these cases are due to the hyperkeratosis of syphilis, and others to ringworm, see Plate III, figs. 2 and 3.

(3) Localised plaques of keratoderma on the hands and feet. Some of these are due to ringworm and others to an Actinomyces. In many text-books they have been described as gouty eczema, etc. The fungi can be found by McGuire's method, see Plate II, fig. 2.

(4) Keratoderma cribrata (Castellani) or keratoderma punctata (Chalmers) forming localised areas of hyperkeratosis. These can be removed or fall out, leaving shallow pits as if a split seed has been lifted out of the epidermis. In India the condition is always due to syphilis, but it may also be due to yaws according to Gutierrez (1923 and 1925) see Plate III, fig. 4.

There should be no difficulty in diagnosing these different conditions of hyperkeratosis from keratolysis of the horny layer of the palms and soles of the feet. Moreover the fungus can readily be demonstrated in these cases of keratolysis.

Treatment.—In hospital, the condition can easily be cured by painting the lesion over with 5 per cent. formalin, as the patients have the opportunity to keep the soles of the feet dry for they are not walking about on damp soil. Prevention is possible by painting the thick skin of

the soles of the feet with 5 per cent. formalin as the fungus is very slow in growth. This could be done once a week during the monsoon months, i.e., from July to the beginning of October.

Discussion.

Although the title of this paper deals with a single clinical lesion called keratolysis plantare sulcatum (Castellani), a lesion very common in the rural districts of Bengal, this study of its causative agent is going to yield very valuable results in the classification of the Actinomyces. The confusion that exists in the literature of Madura-mycosis is too awful for words; the following genera have been cultivated:—*Aspergillus*, *Sterigmatocystis*, *Glenospora*, *Madurella*, *Indiella*, etc. Many have been cultivated from septic sinuses, as we did when cultivating *Aspergillus nigr*a from cases of keratolysis plantare sulcatum. These fungi have been further subdivided according to the colour of the granules, black, red or white. Furthermore, slight variations in the colour and character of the growth have been considered sufficient to subdivide the genus into two separate species. Often the growth of a fungus has been accepted as proof that it is the causative organism, without testing its pathogenicity in animals. We have been able to find an Actinomyces fungus in such different lesions as keratolysis plantare sulcatum, onychia of the nail, intertrigo, hyperkeratosis of the nail bed and plaque-like lesions of the hands, similar in appearance to each other in microscopical examination by McGuire's method. Whilst the microscopical appearances of the cultures from keratolysis plantare sulcatum are identical with the *Actinomyces bovis* type culture, the culture appearances of this fungus are very like those obtained from Madura foot. The question arises whether the same fungus can produce mycetoma on deep inoculation, and keratolysis plantare sulcatum when the horny layer is macerated by dampness. Mycetoma in India is correlated with two factors, a dry sandy soil and the presence of babul thorns (*Acacia babuli*). In Bengal the soil is water-logged and suitable for rice cultivation, whilst deep injuries of the foot are not common and rarely go further than the prickle cell layer on the thick skin of the tread of the foot. The present classification of the Actinomyces adopted by Bergey is very unsatisfactory. He divides them under three heads, (a) pathogenic to man, (b) plant parasites, and (c) saprophytes. Now we know that the *Bacillus pestis*, causing rat plague, can be transmitted to man as bubonic plague, whilst the saprophytic *Staphylococcus albus* can produce superficial stich abscesses. The pathogenic Actinomyces are divided by Bergey into those that produce club-shaped ends in the tissue and those that do not do so, as well as by their growth on various media, and their pathogenicity for animals. We would suggest that the following tests should be adopted for their study.

(A) Morphology, *appearance in the tissue* as segmented or non-segmented hyphæ. The unsegmented hyphæ indicate that conditions are favourable for growth and the mycelium is young, whilst segmentation indicates age or unfavourability.

In cultures.—A study of young and old cultures on different media. Usually one finds unsegmented hyphæ, branching, and later on conidia. The latter may be absent if the medium is not favourable for conidia production, and difficult to see if not stained properly.

(B) Staining reactions. Examination of the fungus in the tissue as well as in culture media by McGuire's method, and also for acid-fast rods. As these are higher fixed plants, there is no need to study whether they are motile or non-motile.

(C) Cultural characters. The general characters should be first considered, whether these fungi are anaerobes, facultative anaerobes, or strict aerobes, and whether they grow best at blood heat or at room temperature. Their growth on the different media should next be studied.

(1) In fluid media, such as peptone water, ordinary peptone broth and litmus peptone broth, some fungi can form pigment from litmus, whereas they fail to do so in ordinary liquid media.

(2) On solid media—agar slopes, potato, acid and alkaline, and carrot.

(3) Solid media containing sugars—whey agar containing saccharose, Sabouraud's test medium of glucose and maltose. Most of the fungi-forming pigment do so on one or other of these media.

(4) Lytic action. The Actinomyces have a lytic action on most proteids, etc. This is of more importance than the reduction of sugars or the formation of pigment. Thus the true Actinomyces clinically do not rarefy bone or dissolve the horny layer of the skin, whilst the Maduromycosis apparently do so, hence it is necessary to study their action as regards their different enzyme action, i.e.—

(i) Proteolysis on gelatin, milk, egg and serum.

(ii) Amyolytic action on starch.

(iii) Keratolytic action on the horny layer of the epidermis.

(iv) The rarefaction of bone-in culture.

(D) The pathogenic effects in animals, taking into consideration these various methods of infection on the skin surface and in the deeper tissues. Moreover we do not know whether these fungi are only infective in certain stages of their growth, i.e., by conidia, hyphæ, etc.

Moreover Pallacci and Nannizzi (1926 and 1927) have shown that for certain ringworm fungi, asci and ascospores are formed when the fungus grows at room temperature on hair, feather, leather or damp soil. In the same way, these fungi will have to be studied on media

PLATE II.

Fig. 1.—A very marked case of keratolysis plantare sulcatum. Notice the furrows on the tread of the foot.

Fig. 2.—A plaque type of hyperkeratosis that showed an actinomycotic-like fungus.

Fig. 3.—Keratolysis palmare. There are no furrows, and notice the dark staining at the sides of the pits.

Fig. 4.—Paronychia of the nails produced by a similar fungus.

PLATE III.

Fig. 1.—Symmetrical hyperkeratosis of the hands and feet. Note the thickening of the skin and the accentuation of the main furrows.

Fig. 2.—Hyperkeratosis of the hands and feet. Secondary to ringworm and associated with certain occupations—betel sellers, cultivators, etc.

Fig. 3.—Syphilitic hyperkeratosis of the feet. Note the numerous deep cracks extending down to the prickly cell layer.

Fig. 4.—Keratoderma cribrata, a late syphilitic manifestation. Note the pit-like depressions in the centre of the palms.

other than those commonly used in the laboratory, such as thorns, etc. There is a good deal of work to be done before we can clear up the exact clinical relationship of such diverse lesions, as mycetoma, actinomycosis, keratolysis plantare sulcatum, some cases of paronychia, intertrigo, and plaque-like areas of hyperkeratosis on the palms and soles. We would be very grateful for any cultures of these fungi obtained from pathological lesions.

CONCLUSIONS.

(1) The lesion known as keratoma plantare sulcatum (Castellani) is not one of the hyperkeratosis, but is caused by a lysis of the horny layer of the thickened epidermis of the soles of the feet, and more rarely of the palms of the hands.

(2) The name keratolysis plantare sulcatum is a better one for describing the lesion.

(3) The lesion is not a manifestation of syphilis or yaws, but is due to an Actinomyces.

(4) In eight cases, examined by McGuire's method, we have found the fungus in all of them.

(5) We have obtained successful cultures in two of these cases.

(6) Microscopically, the cultures resemble the *Actinomyces bovis* of the American Type Culture Collection.

(7) The limpet shaped growth on the surface of the different media used, with deep penetrating roots, which may be black or red resembles those we have grown from cases of Madura foot.

(8) Microscopically we have found similar fungi in certain cases of intertrigo, paronychia and plaque-like hyperkeratosis on the palms and soles.

ON RHEUMATIC INFECTION AS A CAUSE OF MITRAL STENOSIS AMONGST YOUNG INDIANS.

By H. STOTT, M.D., M.R.C.P.,

LIEUTENANT-COLONEL, I.M.S.,

Professor of Pathology, King George's Medical College, and Physician to King George Hospital, Lucknow.

Does acute rheumatic arthritis affect Indians?
 Is unrecognized subacute rheumatic infection in childhood responsible for the mitral stenosis and

chronic congestive heart failure of young Indian adults?

My interest in these questions was first aroused by observing a series of some 20 cases of chronic heart failure in young Indian males, mostly between 12 and 18 years of age, in the medical wards of King George's Medical College Hospital, Lucknow, during the past seven years. They were the victims of congested heart failure following progressive stenosis of the mitral valve. What was the cause of this chronic mitral fibrosis? Was it an evidence of subacute rheumatic infection during childhood? Before this problem could be decided, the question as to whether rheumatic fever exists amongst Indians at all required consideration.

Former views.—The impression formerly held was that Indians were not susceptible to rheumatic fever. Authorities who had examined the cause of chronic valvular disease amongst young Indian adults had concluded that the chronic valvular disease affecting them was a sequel of preceding pneumococcal or streptococcal inflammation. Moreover it was an impression amongst those who had given a thought to the world distribution of rheumatic fever that rheumatic infection would not, in general, exist in such warm climates as in India, Africa, and especially in Egypt. So far as was then known it was confined mainly to such cold and damp climates as are typically experienced especially during the autumn and also during the spring of the British Isles—and of the coast line of North Western Europe.

But acute articular rheumatic fever does affect young Indian adults. I use the word "articular" because an acute febrile infection with multiple hot red swollen joints, exquisitely painful, and affected in rapid sequence, in a young adult, in whom other causes of acute synovitis have been excluded, and when the infection has often followed exposure to cold and damp and has responded to rest and salicylates, forms a clinical syndrome the significance of which is quite clear. I have in mind three such cases in young Indian adults where such a pathognomonic picture was typical. Moreover one of these cases was observed in hospital to develop rheumatic pericarditis and another rheumatic mitral endocarditis. In one case the patient had been soaked in the monsoon rain and had slept on the sodden earth throughout a night preceding his attack. I have seen further cases where a diagnosis of acute articular rheumatic fever was justified, but in these three cases there could be no dispute as to the undoubted evidence they afforded of the existence of acute articular rheumatic infection in young Indian adults. Lieut.-Col. Sandes, I.M.S., Physician to the Medical College Hospital, Calcutta, tells me he frequently recognizes acute rheumatic infection in Indians in his wards. The answer to our first problem is therefore that acute arthritic rheumatic infection does attack young Indian adults.

The subacute rheumatic infection of children in England. The difficulty attending its diagnosis. The frequency with which it terminates in mitral stenosis.

Acute rheumatic fever with well marked synovitis in young adults is an easily recognizable disease. It is, however, far different when subacute rheumatic infection attacks young children, for at this age the infection is most insidious in its onset, the synovia of joints frequently escape or are only slightly affected, and the attack concentrates on such fibrous structures as tendons, fasciæ, ligaments, producing often ill-defined "growing" pains in the joints and limbs. The most characteristic, the most common, and the most dangerous fibrous tissue structure to be attacked by the rheumatic toxin in childhood is that of the mitral valve. Rheumatic myocarditis and pericarditis may occur, but the typical lesion is mitral endocarditis. So common indeed is this association and in order to stress the importance of the usual localization of the permanent lesion in the subacute rheumatism of children that the initial diagnosis of rheumatic carditis is often made instead of the more general diagnosis of rheumatic fever when the infection attacks children. The mitral stenosis shows itself by clinical signs and symptoms some five years after the period of infection, that is usually about or soon after the age of twelve. Then there is no evidence of active infection and at a variable time later the patient is admitted to hospital with irreparable advanced mitral disease and congestive heart failure. Mitral stenosis also frequently follows the articular type of rheumatic fever of young adults.

Of all cases of mitral stenosis in England some 80 or 90 per cent. give a history of previous rheumatism. It is probable that in the great majority, if not all, of the remaining cases, the symptoms of the mitral rheumatic infection in early life were so insidious and so slight as to be entirely overlooked or regarded as due to some trivial ailment. Thus, even in England, where both parents and doctors are alive to the existence and seriousness of the condition, such subacute rheumatic infection of early childhood escapes recognition. It is therefore easily understandable that in India these cases have not yet been generally recognized. And this is the more so since, as is well known, rheumatic fever affects mainly the poorer classes and not those of the well-to-do, whose children naturally come under more careful observation.

Unrecognized subacute rheumatic infection in childhood is the probable cause of mitral stenosis in young Indian adults.

In England rheumatism in childhood is the cause of mitral stenosis. With the knowledge that acute articular rheumatic infection attacks young Indian adults and with the knowledge that mitral stenosis is far from uncommon amongst Indians in their early teens, it is extremely probable (provided other possible causes

for mitral stenosis have been considered and excluded, see following paragraphs)—that subacute rheumatic infection is not uncommon amongst Indian children, and that owing to the vagueness, insidiousness, and slight degree of the initial symptoms, and owing to the class of patient typically affected, the disease has so far in general been overlooked.

Review of other possible causes of mitral stenosis.

Before the presumption that unrecognized subacute rheumatic infection in childhood is the cause of mitral stenosis in young Indian adults can be allowed to stand, other possible causes of mitral stenosis must come under review. Such causes may be conveniently considered under the heads (a) congenital abnormality, (b) degenerative disease, (c) infections—streptococcal, pneumococcal, scarlet fever, influenza, and syphilis.

(a) *Congenital abnormality*.—Congenital heart disease in general produces a clinical picture in which the child is stunted in physical and in mental development, with an enfeebled circulation and such signs of chronic stasis as clubbed fingers. Congenital heart disease is recognized at an earlier age period than the cases of mitral stenosis which occur about puberty. Moreover congenital disease commonly affects the pulmonary valve. The mitral valve is very rarely affected. I have not seen a case, either clinically or at post-mortem. It is of interest to note that French physicians in general consider that mitral stenosis of young women may be of congenital origin, a view which British physicians regard with scepticism.

(b) *Degenerative disease*.—Valvular disease from cardio-vascular degeneration nearly always affects the aortic and rarely the mitral valve, except as a secondary and mechanical extension. Moreover cardiovascular degeneration develops in persons over 40 and not in the age period at present under consideration.

(c) *Streptococcal infection*.—In the literature on mitral disease, the possibility of mitral sclerosis arising after such acute infections as streptococcal septicæmia, pneumonia, scarlet fever, or influenza receives recognition. Certainly the streptococcal group does give rise to an acute or subacute valvular endocarditis, but this is a progressive endocarditis of a malignant type, terminating it may be after a year or so in a fatal issue. The illness is liable to be still more acute and malignant if the infecting organism is a staphylococcus.

Pneumococcal infection.—The pneumococcus does give rise to an acute valvulitis with vegetations. It is just possible that such a case might progress to chronic valvular disease, but the evidence for this is by no means certain; pneumococcal endocarditis is in general a fatal disease. If the pneumococcus were at all a usual cause of valvular endocarditis one would expect to observe this condition develop after the severe and frequent cases of lobar pneumonia and of pneumococcal septicæmia one sees in young

adults. I have not yet observed this occur clinically; though it does undoubtedly occur, yet it is by no means common. Moreover a preceding history of so definite and so acute a disease as lobar pneumonia would be easier to obtain than the vague symptoms associated with sub-acute rheumatic infection of childhood and if pneumonia were at all a common antecedent of mitral stenosis, its history would not be readily overlooked.

Scarlet fever.—As regards scarlet fever the view of some physicians of wide experience in infectious fever hospitals is gaining ground that when permanent valvular disease develops after scarlet fever it is probably an evidence of preceding or of concomitant rheumatic infection. Moreover it has yet to be shown that scarlet fever exists at all amongst Indians.

Influenza.—There is no proof that influenza gives rise to a valvulitis, though it certainly produces an acute myocarditis in the same way as the diphtheritic and to a far less degree the enteric toxin does. If the influenza toxin produces mitral stenosis, it would do so by causing a progressive fibrosis of the mitral ring itself, but there is no evidence that this occurs.

Syphilis.—As syphilis is so frequent a cause of fibrosis, especially in the cardio-vascular system, I have re-considered the possibility of congenital or of acquired syphilis being a cause of mitral stenosis with special care. Apart from some rare pathological curiosity such as a gumma obstructing the mitral orifice (which I have myself seen in a post-mortem heart) the literature does not recognize syphilis as a cause of mitral stenosis. Aortic regurgitation is of course a common and clearly proved sequela of vascular syphilis, but mitral stenosis does not develop in the age period in which the effects of vascular syphilis becomes obvious.

As regards congenital syphilis, it has been uniformly outside the experience of the cardiologists and of syphilologists with whom I have discussed this point that congenital syphilis is a recognized cause of mitral disease in the young. Even Professor Warthin of Michigan University, U. S. A., who has done so large an amount of original work on cardiac syphilis, and is so enthusiastic in his findings of the frequency of syphilis as a cause of cardiac disease, told me that he had never seen a case of mitral stenosis which he regarded as due to syphilitic infection. Moreover in my own wards and in those of my colleagues at King George's Medical College I have examined a series of some 20 cases of mitral stenosis without finding any clinical signs of syphilitic stigmata in them. A Wassermann test of their blood sera showed only one positive in twenty examinations.

Conclusion, with a note on world distribution.

The generally accepted view that syphilis, whether acquired or congenital, is not a cause of mitral stenosis is upheld. Moreover my own

experience and the impression gained from conversation with many cardiologists coincide in indicating that mitral stenosis of long standing is a most unusual sequela, even if it ever occurs, of such infections as with streptococci, pneumococci, scarlet fever or influenza. Degenerative disease is not a cause of mitral stenosis, nor is there sufficient evidence to assign this lesion to a congenital defect. There is then nothing in an examination of the other possible causes of mitral stenosis which weighs against the probability of unrecognized sub-acute rheumatic infection amongst Indian children being the great cause of mitral stenosis in young Indian adults.

As regards the world distribution of rheumatic fever it would certainly appear commonest in the British Isles. It is certainly far more uncommon in those parts of India that I know than in England. Medical men from Canada, the U. S. A., South Africa and Australia have told me that it is relatively rare in those areas as compared with Great Britain. It is certainly common in Belgium and apparently rare in Egypt, which after all what one would be led to expect.

SOME SAFEGUARDS AND POINTS OF TECHNIQUE IN THE EXTRACTION OF SENILE CATARACT WITH CAPSULOTOMY.

By M. D. ANKLESARIA, D.O.S.M. (Eng.),

M.R.C.S. (Eng.), L.R.C.P. (Lond.), F.C.P.S. (Bom.),

Honorary Ophthalmic Surgeon, Civil Hospital and
Lecturer in Ophthalmology, B. J. Medical School,
Ahmedabad.

It ought to be the rightful ambition of all ophthalmic surgeons to secure the highest percentage of success in the extraction of senile cataract both as to quality and quantity. Considering the fact that the eye is a highly evolved and extremely delicate organ, and restoration of vision as near the normal as possible our sole object, in dealing with it no precaution or detail is too trivial and no care or precision too much. While this paper claims nothing original or new, nothing that has not been said elsewhere, it claims the necessity of recording in these columns safeguards and modification of technique abundantly tried and found successful, in the hope that wider publicity may result in greater benefit to the blind.

Preparation of the patient.—General cleanliness of the body as a whole and of the head and face in particular should be enjoined. Oral sepsis, septic tonsils, and toxæmia from the alimentary and genito-urinary tracts form important sources and predisposing factors of endogenous infection and should deserve our careful consideration. Oral sepsis may be due to inflamed gums, stomatitis and ulcerations of various forms, caries of teeth and decayed stumps, dental or apical abscesses, pyorrhœa and general want of cleanliness of the teeth, and

should be suitably dealt with before the operation. To keep the mouth as clean as possible, a routine use of mild antiseptic gargles such as of weak potassium permanganate lotion should be prescribed twice or thrice daily for the whole course of treatment. Diseases of the nose and the accessory sinuses should be treated beforehand. Atrophic rhinitis, a very frequently neglected form of ozæna, should not be lightly considered but should be treated first with a little iodine paint applied to the nostrils once or twice daily for a few days before and during the course of operation. A gouty diathesis is more apt to cause severe iritis after the operation. The presence of albumin or sugar in the urine is a matter of great anxiety to the operator. These conditions not only impair the healing power of the wound, but cause serious complications such as severe iritis and cyclitis with exudation which mar the success of the operation. On the other hand both these conditions can be made amenable to a proper regulation of diet and suitable drugs before the operation, and during the course of the after-treatment in order to tide over the period of complications. Numerous eyes have been lost for want of observance of this elementary precaution. In case of syphilis it is always advisable to have some anti-syphilitic treatment carried out prior to operation for fear of a severe iritis resulting later on. Patients with high blood pressure, also big burly individuals with short thick necks are losing hazards and should be accepted with caution. In such cases a course of thyroid gland for a few days previous to operation would be good. The bowels should be thoroughly evacuated the previous day, to avoid getting up on the day of the operation.

A great measure of success depends upon the proper and judicious selection of cases. All cases of inflammatory processes beyond those caused by traumatism due to the operation can now be safely attributed to infection from the conjunctival or the lacrimal sac, both of which are important habitats of microbic population, and hence the commonest sources of exogenous infection to which are due the majority of our failures to restore the sight. To the extent that this is preventable the responsibility is ours.

With our modern methods of high pressure sterilisation of dressings and thorough sterilisation of instruments chances of infection from these sources are practically non-existent. As the conjunctiva is seldom free from pathogenic germs, a bacteriological examination of the conjunctival sac as a safeguard should be most desirable wherever possible as a routine method, though unfortunately it is not available to us as yet. A few white staphylococci or xerosis bacilli of low pathogenicity may not matter, but *Staphylococcus aureus* or *citreus* or streptococci or pneumococci or ozæna bacilli are all contraindicated for an operation. When such an examination is not available slight hyperæmia or very little thickening of the conjunctiva or the

presence of mucous or a muco-purulent discharge at the inner canthus, so often seen in the case of patients who have had trachoma, should forewarn against operation. The absence of movements of the lids and the diminished lacrimation when under a bandage and the rise in temperature and increase in the congestion of the conjunctiva consequent upon closing the lids and traumatism are all favourable factors for an increase in the existing microbic population, aggravate their virulence and harmful effects, and give rise to infective process of varying degrees which eventually prolong the convalescence and mar the success of the operation to a greater or less extent.

As further safeguards against infection the lacrimal sac should be carefully examined for any regurgitation or discharge of mucous or mucus. But this is not enough. The patency of the nasal duct should be established beyond doubt in all cases by syringing and noticing a free passage of fluid in the nose or by putting a little fluorescein solution or argyrol or mercurochrome drops at the inner canthus and then asking the patient to blow the nose after a little while and noting whether the secretion is stained or not. I prefer to instil mild antiseptic drops of mercurochrome gr. 2 to oz. 1 twice daily until the time of operation.

For those patients who are very nervous a dose containing bromide, morphia and chloral should be prescribed as a routine one hour before the operation to allay their irritability. A little time wasted on training the patient to look up and down as directed without moving the head and to gently close the eye when directed to do so is always well spent.

Preparation of the eye.—The face should be well washed with soap and water. The anaesthesia is carried out by instillation of 3 or 4 drops of a freshly prepared and sterilised solution of cocaine 4 per cent. and adrenalin m. 2 to 1 c.c., four such instillations being put in the eye to be operated at five minute intervals, and twice in the other eye, both being kept closed. After the first instillation of cocaine and adrenalin the lids are everted and the conjunctival sac, including the fornices, the caruncle and the margins of both the lids, thoroughly exposed and washed out with hydrarg. perchloride lotion 1 in 5000, the contents of a 4 ozs. undine. The importance of irrigation of the conjunctival sac with perchloride of mercury lotion, advocated by Herbert so far back as twenty-five years ago as an important safeguard against infection, remains unchallenged even to-day, owing to the average Indian conjunctiva being far from the normal. Its action is partly mechanical and partly chemical, owing to its coagulative action in which are imprisoned the organisms of the superficial epithelium of the conjunctiva, these latter being removed by the subsequent swabbing with cotton-wool wetted with normal saline lotion. The margins of the lids should be

emptied of the meibomian secretion and the eyelashes of the upper lid, particularly of the outer half, should be cut short. Tincture of iodine should be applied externally over the eyelids and their vicinity. The beginning of the dilatation of the pupil is the signal that the cocaine has acted on the iris and the anæsthesia is complete.

Over and above this instillation anæsthesia, by far the most important safeguard against those who show a tendency to squeeze their eyelids violently or who cannot control their twitchings is an injection of novocaine and adrenalin into the orbicularis oculi muscle with the double object of securing a palpebral akinesis or a temporary paralysis by blocking its motor supply, the zygomatic branches of the facial nerve, and also an anæsthesia of the lids and the canthi by blocking their sensory supply from the lacrimal, the supraorbital, the supratrochlear and the infratrochlear branches of the ophthalmic for the upper lid and the infraorbital branch of the maxillary division of the fifth nerve for the lower lid, after the method of Van Lint of Brussels. About 3 or 4 c.c. in all of a one per cent. novocaine solution containing 1 minim per c.c. of adrenalin solution 1 in 1000 may be injected by inserting the needle at the point of intersection of two lines, one a horizontal line passing 0.5 cm. below the lower border of the orbit and the other a vertical line passing 0.5 cm. external to the outer margin of the orbit. The needle penetrates skin and muscle down to the bone and is pushed towards the horizontal line, and about one-third of the solution is injected drop by drop, the needle keeping close to the bone. The second-third of the same solution is injected in the vertical line close to the external orbital border in two or three spots, and the final third is injected close to the superior orbital border in two or three spots, but more or less superficially. In about 10 minutes the lids will relax sufficiently or become sufficiently weakened so as not to disturb the operation and will remain so for about 30 minutes more. Another little suggestion to overcome this squeezing tendency is to ask the patient to keep his mouth open and breathe through it, as with an open mouth he will not squeeze so hard.

The *bête noire* of all operators who perform extraction with capsulotomy is usually inflammatory processes varying in number and severity, partly due to the traumatism inflicted, partly due to bacterial infection, and partly due to irritation caused by the particles of lens matter left behind. To inhibit these factors, if not to check them altogether, various modifications of technique were introduced. Subconjunctival extraction was advocated as early as 1855 by Desmarres, in 1898 by Pansier, in 1899 by Vacher and in 1903 by Czermak in different forms. More recently this method has been advocated by MacGillivray, Cridland, Killick, and others. The addition of a conjunctival flap was the first step in that direction and its

subsequent conversion to the bridge by keeping the flap undivided and attached to the bulbar conjunctiva was a more effective and ambitious advance on the original. The best way we have found to effectively control them to some extent is by performing the extraction under a conjunctival bridge which causes an immediate sealing of the wound, and by as completely washing out all lens matter as possible from the anterior chamber by irrigating it with saline lotion.

Many may not regard it as good surgery to make such a large section in the avascular cornea and allow it to remain open and in contact with the palpebral conjunctiva, which is by no means sterile. The slight gaping of the wound that may take place about its middle or the top of the arch is liable to be infected by contact with it and aggravated by partially uncontrolled vertical movements of the upper lid. To this the conjunctival bridge affords the most suitable protection by the immediate sealing of the wound it causes. Further, owing to the conjunctiva being intact and the vessels undivided at the bridge, the nourishment of the anterior lip of the wound is unimpaired and hence inflammatory complications of the cornea are of rare occurrence and healing takes place sooner, thus materially reducing the course of the after-treatment, a no small gain indeed. The anterior chamber can also be irrigated with a feeling of security under the protection accorded by the conjunctival bridge, there being no gaping wound and dread of loss of vitreous at any moment. It provides a further safeguard against the over-riding of the edges and the eversion of the flap. The anterior chamber soon becomes restored, a decided advantage, as atropine will not act until it becomes formed. Prolapse of the iris or tags of capsule, if any, are effectively covered over, keratitis of any degree of severity is the exception, and post-operative astigmatism is not above the average.

Among the disadvantages of the bridge must be mentioned the fact that in the first place it is a little difficult of execution and it is also sometimes impaired by consciousness, i.e., when you wish to do it best you often fail to do it. With regard to bleeding at the time of operation the addition of a little adrenalin to the cocaine checks it, and owing to the position of the bridge what little occurs passes out of rather than inside the anterior chamber and there is no increased tendency to bleeding during the after course unless due to trauma. The performance of the iridectomy and particularly the delivery of the lens gives real trouble if the bridge is not sufficiently long. I had it in my earlier cases, but since I hit upon the plan of causing the edge of the lens to get fixed on the side of the incision towards the iridectomy and of using the point of the von Graefe knife to stab and lift the lens out of the wound that difficulty has ceased to exist. I have tried this method in a large number of cases in the past several years and found it most successful for extractions

with capsulotomy. Much has been said for and against the bridge in the last few years by men whose opinion is entitled to great respect. My experience however leads me to recommend the bridge and I have therefore ventured to express my views with considerable diffidence.

Incision with a conjunctival bridge.—A small incision spells disaster. It is apt to cause trouble in numerous ways. Undue force has to be used in the delivery of the lens, bruising the edges of the wound and causing a large amount of cortical matter to be left inside and stripe keratitis likely to result therefrom. A liberal sized incision should be the rule. The patient should be asked to look down as far as possible. The incision should be made with a von Graefe knife so as to carry a small fold of conjunctiva at the puncture and the counter puncture and carried into the corneo-scleral margin above, and then prolonged underneath the conjunctiva as far back as possible and left undivided, there to form a fairly broad bridge of intact conjunctiva above. This is difficult when the lids are narrow and the eye lies deep in the socket, in which case the bridge may be lengthened upwards by means of scissors cutting on either side and equally. It is necessary that the bridge should be long and even on both sides. Owing to the use of adrenalin in cocaine and the conjunctival vessels being left undivided, little hæmorrhage occurs if any.

Iridectomy.—The main purpose of the iridectomy is to prevent a prolapse of the iris by the gushing aqueous after the operation, whilst owing to the conjunctival bridge a small peripheral iridectomy after the extraction is impossible. A complete iridectomy is to be preferred in this also that it permits the use of capsule forceps to tear out as large a piece of the anterior capsule as possible. Owing to the conjunctival bridge the iridectomy has to be made a little to the outer or inner side of 12 o'clock.

Capsulotomy.—I always use a capsule forceps, preferably with many teeth, except in Morgagnian cataracts which are punctured with the point of the knife. The closed forceps are passed into the anterior chamber and are gently opened and lightly pressed upon the anterior capsule to obtain as big a bite of it as possible, and with gentle side to side movements it is torn out of the wound. By removing a good sized piece of the anterior capsule of the lens a wide opening is made for removal of the cataract and the evacuation of the remaining lens matter is favoured.

Delivery of the lens.—The conjunctival bridge causes a certain amount of difficulty in the delivery of the lens and is hence an important cause of annoyance to many. I tackle it easily with the spoon and the von Graefe knife. With the spoon in the left hand pressure is applied over the lower and inner part of the edge of the lens, and with the back of the knife near its point, the upper and outer lip of the wound is depressed and the edge of the lens is

made to engage in it and kept steadied there by the lower spoon. The knife is now used as a lance to rotate the edge of the lens towards the puncture and stab and lift it out of the wound. The anterior chamber is then irrigated with the nozzle of a small cannula attached to a flask containing 0.6 per cent. sterilised saline by means of a rubber tubing. If one dresses one's own cases one cannot fail to be struck by the comparative freedom from inflammatory changes in cases in which the anterior chamber was clear from the first, as shown in cases of Morgagnian cataracts, and by the severe reaction displayed by those where much lens debris remained in spite of washing out. Though this latter method has not found favour with surgeons in the West, I have no manner of doubt about its efficiency and harmlessness. As complete evacuation of cortical matter as possible should be the dictum to follow and can be accomplished with impunity under the protection accomplished by the conjunctival bridge. All lens debris behind the iris and situated at the periphery should be coaxed towards the pupillary area by gentle stroking movements made on the cornea and at the periphery with the bend of the spatula or by the back of the spoon and then washed out of the anterior chamber by the gentle stream from the cannula of the irrigator. The stream from the irrigator running in the anterior chamber is regulated by the finger tips and thumb holding the rubber tube over the cannula. By alternately pressing and relaxing the rubber tubing, i.e., making and breaking the current or playing it in a side to side fashion or depressing the lower lip of the wound all lens debris and blood, if any, is successfully washed out. A little patience and care in this step of the operation is always well spent, as can be judged from the comparative freedom from injection and infective complications to which such eyes are subject. On the contrary blood clot and lens debris form good culture medium for organisms of low virulence to grow, and, with the traumatism, favour fibroblastic activity and proliferation of epithelial cells, and infective processes of varying degrees develop and iritis and exudation result therefrom. Careful reposition of the pillars of the iris is a very important safeguard against incarceration or prolapse of the iris, which though slight in degree are serious enough for the ultimate fate of the operated on eye. The wound in such cases takes a long time to heal and does not become firm, the pain and irritation in the eye is kept up indefinitely and the cicatrix may become ecstasic. Secondary glaucoma or late infection may occur, or sympathetic trouble may develop in the other eye. The edges of the wound should further be cleared so that no intraocular content such as a tag of capsule or cortical matter or vitreous may get entangled in the wound and prevent its early union. Delayed union and late formation of the anterior chamber and infection are apt to result from such causes. The aqueous keeps on escaping

continuously through a small fistula at some point in the wound, and contact keratitis develops owing to the anterior chamber long remaining unfilled.

After the completion of the operation it is advisable to instill 2 or 3 drops of a one per cent. sterilised atropine solution so as to open up the pupil early enough to prevent synechiæ forming, and if the pupil is not dilated the next day, atropine should be put twice or thrice watching its toxic effects. Both eyes are bandaged and the unoperated on eye is kept open after the anterior chamber has formed in the operated on eye. The patient begins to feel some pain after the anæsthetic effect of the cocaine has passed away, due to the contact of the iris with the cornea, but it disappears as soon as the anterior chamber becomes restored. The dressing should be changed daily and any mucus over the lid margins carefully cleaned and 2 or 3 drops of atropine, 1 per cent. should be continued till all trace of ciliary injection has disappeared.

If there is much catarrh of the conjunctiva, mercurochrome 1 per cent. or argyrol 10 per cent., or zinc drops gr. 2 to oz. 1 may also be instilled. The edges of the wound should be carefully examined to see that no infection has started there. In all suspicious cases parenteric injections of sterilised milk 8 to 10 c.c. may be given in the gluteal region which nearly always check the pyogenic process like a charm.

ARS GYNÆCOLOGICA.

By V. B. GREEN-ARMYTAGE, M.D., F.R.C.P. (Lond.)

LIEUTENANT-COLONEL, I.M.S.,

Professor of Obstetrics and Gynæcology, Calcutta Medical College and Surgeon to the Eden Hospital.

Operative results.—Polak in a very interesting paper has analysed 95 deaths out of a total of 3,125 patients operated upon. He considers that the fatal issue can be attributed to one of the following causes:—

(a) Employment of the high Trendelenburg position in a patient with high blood pressure produces cardiac embarrassment, and the prolongation of this posture in patients with low blood pressure increases the occurrence rate of shock. This information is of particular importance to us in India.

(b) Too much surgery has been done at one sitting.

(c) The time consumed in operating has overreached the maximum of safety.

(d) Forty-eight hours' rest is imperative before any major operation. This rule is frequently disregarded in India.

(e) Patients who have been the subject of prolonged infection and have either a high or low leucocyte count, and particularly a low polymorphonuclear count, have a poor reaction to operative procedure. The optimum leucocyte count is 7 to 10 thousand, and the optimum polymorphonuclear percentage is 65 to 80.

He lays stress on the importance of every patient taking not less than three quarts of fluid (water, milk, fruit juice) per day for 2 to 3 days before operation, and considers that during this period the usual cane sugar intake of the individual must be quadrupled. This latter statement is of interest to the writer, for he has during many years insisted on all patients about to undergo major operations, taking 3 to 4 ozs. of natural honey (*modhu*) for 5 to 7 days before operation in order to increase the liver glycogen reserve, and inhibit the risks of acidosis and shock, and his results have justified the procedure now advocated by Professor Polak.

It is interesting to observe that 8 of the deaths recorded were due to paralytic ileus. Such ileus is due to partial obstruction, for although there may be a passage of gas from the rectum, and even bowel movement, vomiting continues and the gas tympanites quickly re-accumulates.

In such cases the pulse and temperature are not much alleviated, yet regurgitant vomiting continues and gas pains persist. The only treatment is early exploration under local anæsthesia, when it will be revealed that there is some loop of the intestine slightly adherent to the abdominal wall or to a point in the operative field. Release of this, with or without puncture enterostomy, or cæcostomy, will save the majority of these patients if only the surgeon has the courage to do so immediately a clinical diagnosis is made. Professor Polak is definitely against operation in the acute or sub-acute stages of adnexal infection. Should operation, however, become imperative because of pus formation, or obstructive peritonitis, he advocates only simple drainage from above or below.

Sterility.—During the last year, several papers of importance have appeared on this subject, so perhaps it will be useful to refer to conditions which are common but are rarely understood by the general practitioner, who is as a rule the first person to be consulted on this matter.

For instance, under-development of the uterus is a much more frequent cause of sterility than is generally supposed, but it must be remembered that there are minor degrees of under-development, which though unfavourable are not hopeless. For an under-sized uterus associated with infrequent and scanty menstruation may represent a delayed rather than an arrested development. In such a case the stimulus of marriage is probably the most successful treatment, but as I have previously pointed out, growth and function may be assisted by the administration of thyroid gland, half a grain twice a day for twelve weeks.

Pituitary, ovary and corpus luteum extracts are useless by the mouth; if they can be given hypodermically, from freshly prepared sheep's ovary, they may have some value.

Progressive or pronounced obesity is antagonistic to reproductive activity, but fat sterile women can become pregnant if their adiposity can be reduced. I have seen quite a number of such fat cases where fertility has occurred follow-

ing prolonged illness with high fever. For instance after enteric, malignant malaria and kala-azar, the adipose tissue is burnt off, so to speak, and the uterine function rejuvenates. In this connection it is not without interest to quote a few references from Shakespeare; for instance you will remember Dr. Cerimon in *Pericles* says—

“Who can speak of the disturbances that Nature works, and of her cures.”

And the lines in “*All’s Well That Ends Well*”

“Our remedies oft in ourselves do lie,
Which we ascribe to Heaven.”

When I am consulted for sterility by a patient who is unduly stout, I always advise as a first step, reduction of weight, not so much by the omission of this or that article of diet, as by diminution of the total amount of food taken, supplemented if necessary by the administration of thyroid gland and protein shock therapy which enhances the rate of fat metabolism.

It should be remembered that early-marriage-contraceptive-measures, if continued for any length of time, are inimical to pregnancy. Oft repeated and constant coitus induces a condition of hyperplasia of the ovary, and what has been called by the undignified name of the “*Marie Stopes’ uterus*.” In such a case of sterility it is only fair to the patient for the practitioner to make enquiry and advise accordingly; for it has been discovered that less than 20 per cent. of women who use contraceptive measures for a consecutive period of three years ever become pregnant.

Artificial insemination, though not a very pleasant business, has its uses for cases where the act of coitus is difficult or unsatisfactory, for many reasons which I need not go into here. If the semen is positive, success may occur. The husband is put in one room and the wife in another. She is placed in the lithotomy position with a speculum in situ and a tenaculum on the cervix. Directly the semen is received into a warm test-tube, it is aspirated into a glass syringe fitted with a four-inch soft rubber catheter which is then carried into the adjoining room, inserted into the cervix above the level of the internal os and slowly injected into the uterus. This procedure is adopted on the fifth, eighth and eleventh days after the last day of the menstrual period.

It is possible that some cases of sterility are due to a plug of mucus which blocks the cervical canal, and so prevents entrance of the spermatozoa; in such cases insemination is useful as the nozzle of the rubber catheter passes through and above this plug into the cavity of the uterus. Some gynaecologists, recognizing the importance of eliminating this mucus plug from the cervix, insist on every patient using prior to coitus, a douche of 2 per cent. bicarbonate of soda in warm water.

If the external os is unduly contracted or of the pin hole type, dilatation should be done, but without laceration. In cases of one child sterility, or of abortion, and no child, it is common to

find a flabby patulous external os. For these striate electric cauterisation is useful.

For many years now we have been using the Rubin insufflation test, which, apart from its diagnostic importance, has a therapeutic value of at least 10 per cent. Recently, however, a new therapeutic method has come to the fore which has even greater therapeutic and diagnostic value. I refer to the use of lipiodol.

Forsdike uses a Record syringe, but I use Statham’s modification of Becler’s instrument. If lipiodol is used diagnostically an x-ray photograph should be taken or fluoroscopy done at the time, or within 24 hours; when the tubes are patent the solution will be seen in the pelvis or pouch of Douglas. If they are blocked, the site of stricture will be demonstrated on the hystero-gram. The accompanying photographs taken in co-operation with Dr. G. Galstaun will make my meaning clear.

Number 1 is that of a lady who had had a Gilliam operation performed in another part of India for sterility plus retroversion of the uterus some years ago without result. The hystero-gram demonstrates that the uterus is or has been pulled too much over to one side and that the right tube, though patent and beautifully shown, is kinked and deviated to the left. Lipiodol is seen emerging from the left tube ostium.

Number 2 shows the lipiodol free in the peritoneal cavity 12 hours later. It is noteworthy that the solution causes neither pain nor after reaction.

Number 3 is that of a case of one child sterility. I found that she was negative to Rubin’s test at 250 mm. Hg. pressure; as nothing was palpable it was necessary to discover whereabouts the block in the tubes was, before giving a hopeless prognosis. The lipiodol test very perfectly demonstrates that the block is at the fimbriated ends of both tubes and that no lipiodol can escape the so-called phimotic tubes.

Number 4 taken 12 hours later, confirms the finding. In this case the importance of the test is amply shown, for after the simple plastic operation of salpingostomy this lady can look forward to conception; whereas had the block been shown in the photograph to be in the isthmial portion of the tube it is probable that no operation however ingenious would have been successful.

Number 5 is another case of sterility, the history being that 3 years ago she was operated upon urgently for a ruptured extra-uterine pregnancy. Vaginally, the uterus appeared smaller than normal and somewhat deviated to one side, which would not be an unlikely finding after such a catastrophe. A Rubin test was positive at 200 mm. but not being quite satisfied I confirmed the finding with lipiodol and you will see that the cavity of the uterus is large and directed towards the patent left tube. There is no indication of the normal triangular appearance of the cavity of the uterus, presumably, therefore, she was a case of pregnancy in one horn of a

PLATE I.

Some clinical types of the cervix uteri. Adapted from Tavssig, Crossen and Dickinson and painted by Mrs. Clarke of Kurseong.

Fig. 1.—(a) An erosion in a nullipara; (b) an erosion with eversion of the mucous membrane due to long standing endocervicitis in a nullipara; (c) cervix with a mucous plug in a case of sterility; (d) half section of such a cervix showing mucous plug as a result of hypersecretion of the endocervical glands blocking the passage to internal os. Many contraceptives in common use may cause this.

Fig. 4.—(a) Bilateral lacerated cervix with everted mucous membrane (Kelly), a fertile field for the development of cancer. Such a case is treated best *not* by actual cautery but by early amputation (Bonney method) or by vaginal hysterectomy or radium. (b) Lacerated cervix with ovula Nabothi; (c) a duck bill lacerated everted cervix, often a precancerous condition; (d) a lacerated stellate cervix with eversion of mucous membrane, often precancerous.

Fig. 2.—(a and b) The cervix of a parous woman showing eversion and many ovula Nabothi, such patients frequently have pain in the back and profuse periods due to hyperplasia of the endometrium; (c) shows varicose vessels and a few ovula Nabothi stabbed with cautery; (d) the typical conical cervix with so-called pin-hole os, associated so often with sterility, dysmenorrhœa, and the infantile or subpubescent uterus; (e) a cervix with a mucous polypus presenting at external os, causing continuous sanious discharges.

Fig. 3.—(a) The lacerated everted cervix of a multipara showing large readily bleeding papillary erosion, the outward and visible sign of an inward and invisible infective endocervicitis, the so-called precancerous cervix; (b) the same after the endometrium and endocervix have been curetted and the cervix has been radially electro-cauterised; (c and d) the same seen 4 and 8 weeks after actual cautery.

Fig. 5.—(a) An early case of squamous-celled cauliflower cancer of the cervix (Ruge); (b) the ulcerative type of cancer of the cervix (Ruge). Radium treatment by an expert is the best means we possess of giving a fair prognosis, with subsequent deep x-ray therapy. (c) An ulcerative type of cancer beginning at a scar at the left edge of the external os.

bicornuate uterus and the prognosis is in consequence extremely doubtful. The hystrogram diagnosis was confirmed by the history of a supposed normal pregnancy in the uterus (she was seen by a London consultant before sailing for India) which terminated by sudden rupture on board ship at the 20th week, just outside the port of Calcutta.

Number 6 is that of a case of one-child sterility sent to me from the Punjab to do a Gilliam operation upon for slight retroversion. There was no prolapse of the ovary, and the lipiodol was positive at 150 (Beclere instrument). The hystrogram shows both tubes patent, and the one more easily than the other. Obviously, therefore, no surgical interference is necessary. This case demonstrates the practical importance and prognostic value of the lipiodol test.

These hystrograms will I trust interest and instil enthusiasm into the scientifically minded members of our profession who are in touch with teaching units, for there can be no doubt that they enhance the art of gynæcology. Nowadays it is no longer necessary to operate in order to "look see," for the good clinician with the help of the radiologist can make an accurate diagnosis and prognosis before advising operation.

Quite apart from its diagnostic value in many morbid conditions of the pelvis, which I need not here go into for Statham and Forsdike have written of these, I should like to state that the simple painless injection of 5 to 10 c.c. of lipiodol through the healthy cervix into tubes which have been proved patent by Rubin's test about the fifth to the ninth day after the last day of the period is of very decided therapeutic affect, 30 per cent. of patients becoming pregnant as a result of this measure alone, provided coitus does not occur until 6 to 8 weeks after the injection. It should be noted that whereas the affect of the Rubin test is at the most 3 months, the effect of the lipiodol lasts for nine months. The reason for this may be that the iodine tones up or invigorates the tubal mucous membrane or the surface of the ovary and so renders the transit and nidation of the ovum and spermatozoa more easy.

The writer having performed a very large number of these two tests, would like to emphasise a clinical maxim of great importance, namely, if in any case of retroversion or retroflexion of the uterus with sterility a Rubin test is positive at or about 100 mm. Hg. pressure, then there is no justification for pelvic engineering, e.g., Gilliam's operation. But if the test is only positive at or over 150 mm. Hg. then operation is indicated, for it means that there is probably a partial kink forming a mechanical block in the tube, while the uterus is in the backward position.

Occasionally when all methods of diagnosis and treatment have been investigated and tried, an abdominal operation will demonstrate some ovarian lesion which was impalpable bimanually.

I have had quite a considerable number of such cases, who have become pregnant after operation. For instance I have found small soft cysts in one or both ovaries, varying in size from a cherry to a ping-pong ball, full of clear gelatinous fluid. These are shelled out with ease, and for some reason not perfectly understood, healthy normal ovulation occurs afterwards.

In others the ovary has been found shut off from the peritoneal cavity and fimbriated ends of the tubes by delicate veils of peritoneum, denoting previous inflammation. When these have been removed pregnancy has occurred later.

Occasionally the ovaries have been found treble their normal size, prolapsed, and almost dropsical in appearance. Hemi-section and suture elevation of the organs has given happy results. There is, however, a clinical condition, namely gross thickening of the tunica albuginea which is most disappointing, for scarification or paring off the thick coat is only followed by greater fibrosis, such ovaries are hard and wrinkled, grey and small. I have yet to see one of these patients bearing a child to full term.

Protein Therapy.—It has been shown by Holler, Weiss and Hibbert that the effect of the injection of foreign protein is: (1) to increase the function of the hæmopoietic organs; (2) to increase the number of phagocytes in the blood stream; (3) to increase the number of active antibodies in the blood.

Protein therapy is a very useful adjuvant to gynæcology for those complaints which give rise to suffering, but for which operation is inadvisable or not imperative. For instance:—

- (1) The fixed, tender, enlarged, displaced uterus.
- (2) Tender and enlarged tubes and ovaries, accompanied by occasional fever.
- (3) Thickened and tender utero-sacral ligaments with sacralgia.
- (4) Tenderness and thickening at the base of the bladder.
- (5) Parametrial exudates.

In hospital practice I use plain freshly boiled skimmed milk, but in private a preparation known as Aolan. The first dose, given intramuscularly, is 5 c.c. and after that 7 to 10 c.c. are given every four days, or six doses in all. From a detailed consideration of a great number of cases, I am satisfied that this treatment is of great value. Indeed it is surprising to discover by palpation that after this more or less painless treatment, exquisitely tender inflammatory exudates have melted away and to hear a patient voluntarily tell one that the pain and backache have disappeared. The greater the reaction, the better the result. In the case of a tubo-ovarian mass, pending operation it is of value, because whilst marking time it raises the resistance of the patient.

Carcinoma of the ovary.—A remarkable series of these cases which occurred in the writer's practice during 1928 makes it imperative to consider this condition, for tumours of the ovary

are extremely common in the tropics and there is a tendency to delay sending such cases until they are of great size, thereby running the extreme danger of malignant degeneration.

Doderlein found that 10 per cent. of all ovarian tumours were malignant. Lippert states that 15.5 per cent. are malignant.

Carcinoma of the ovary is rare before the age of 20, and of greatest frequency between the ages of 45 and 50. A feature of malignant ovarian tumours is that their growth is very rapid and almost without symptoms, indeed a tumour may be discovered accidentally.

Ascites may or may not be present; the uterus is as a rule displaced to one side. Irregular menstruation or metrorrhagia may bring a patient to her doctor and it is a *good clinical maxim to remember that irregular menstruation after the menopause is frequently associated with cancer of the ovary if the uterus cannot be incultated.*

The only treatment is immediate operation with the removal of both ovaries and the uterus, followed by post-operative radiation. The death-rate from recurrence is 76 per cent. in the first year and 15 per cent. in the second year. So great is the mortality and recurrence rate that in recent years, where the tumour is hardly removable, palliative injections of selenide of lead combined with deep x-ray therapy have been used.

Todd, who is the originator of the selenium treatment of inoperable cancer both of the ovary and uterus, has had some remarkable results, results anyhow more happy than those of surgery. I have seen some of his cases and it is quite remarkable to observe the shrinkage and stony hardness that occurs in the tumour as the result of the intravenous injection of selenium, prepared by the B. D. H. Company according to the Bristol formula.

Problems associated with the cervix uteri.—At the present moment there is only one known way to combat cancer mortality and that is by the recognition of the process in its earliest stages, or better to identify those lesions which are definitely known to be forerunners of malignancy.

The importance of this statement will be realized when the public and all practitioners remember that one out of every 27 women die of cancer of the uterus. Now, it is a well known fact that women who have never borne children or in whom there has never been any previous inflammatory process within the cervix, rarely develop cancer of that organ. What then is the pre-cancerous stage in a woman who has borne children? Surely it is the presence of chronic inflammation, the result of chronic irritation. This irritation being most probably of a chemical nature, just as coal tar produces carcinoma of the scrotum and a pre-cancerous condition of the epithelium can be produced in the skin of a rabbit by the application of coal tar.

It has been suggested that the constant bathing of the cells of the vaginal portions of the cervix which were intended to remain in an alkaline

solution with a purulent acid secretion is an important factor in the causation of malignancy. Nevertheless it must be remembered that chronic inflammation and irritation is kept up by the presence of hosts of bacteria which harbour in the complicated glandular arrangement of the cervical mucous membrane, and that an erosion of the cervix is neither an ulceration nor granuloma, but rather an adenoma.

We do not yet know the exact cause for the proliferation of cells previously normal to form what we call microscopic cancer, but there seems little doubt that chemical and bacterial irritation and inflammation are the predisposing factors. Therefore it behoves us in every case of erosion plus laceration in a parous woman over the age of 30 to insist on adequate treatment, and by that I do not mean painting with picric acid or carbolic, or the use of diathermy and such like tinkering gynaecology, which prostitute the good name of our Art, but rather excision, amputation or electric cauterisation of the entire diseased area.

Huggins, in 2,985 cases treated on these lines during the last ten years, has never seen one of these patients develop cancer of the cervix, and in an admirable thesis he deplores the carelessness of the gynaecologist in his responsibility to infections within the cervix, and states that it is our duty to teach both the profession and the public that every infected cervix should be adequately treated as it carries with it the possibility of malignancy. He prophesies that the time will soon arrive when women will consult the gynaecologist once in six months just as they do their dental surgeon.

Time and again the writer has insisted on the importance and necessity of an adequate pelvic examination with the use of a speculum in the case of all women consulting their doctor, either immediately or remotely after confinement, or abortion. The accompanying plates I trust will greatly facilitate diagnosis, prognosis, and treatment.

The vesico-vaginal fistula.—Colonel Fraser has published in the *Indian Medical Gazette* recently an illuminating article which is of special interest to all practitioners in India, for the majority of fistulae seen are so large, so high up, so surrounded with dense scar tissue, or so unget-at-able because of a contracted pelvic inlet and outlet, that any improvement in treatment must be welcomed.

His method is that of rectal transplantation of both ureters. He reports 24 cases, with success in 22 and no mortality, and gives in detail his technique. The operation is done in two stages, first one ureter is implanted, and then three or four weeks later the second ureter is dealt with.

The writer having performed this operation in a case of ectopia vesicae with success is greatly impressed with Fraser's technique and results, and is determined to follow him at the first opportunity; moreover he is glad to see that the

PLATE II.

Fig. 3.

A gelatinous material deposited on the top. It was removed and filtered, giving a clear red fluid which became frothy on shaking, giving a suggestion of the presence of a saponin. After keeping the solution for 48 hours the solution decomposed giving a brownish precipitate.

Our next attempt was to isolate* the alkaloid.

Method No. 1.—Half a pound of powdered *nakchhikni* was treated with 1 per cent. sulphuric acid on a water bath for two hours and kept overnight with frequent agitation at intervals. The dilute acid extract was pressed and filtered, and the residue was exhausted with water till free from acid. The acid extract was now neutralized with ammonium hydroxide and the whole evaporated to dryness on a water bath. The dried residue was extracted with absolute alcohol and filtered. The filtrate was diluted with an equal volume of water (to precipitate the resins) and filtered. It was then evaporated, treated again with 1 per cent. sulphuric acid and filtered. It was then preserved for alkaloidal tests (*Fluid No. 1*).

Method No. 2.—Next we proceeded to deal with the watery extract which in our preliminary experiment showed a stimulating action on the frog's heart. Two pounds of powdered drug was boiled with water for six hours. The whole was pressed and strained. On cooling a layer of gelatinous substance collected at the top which was removed. The watery extract was red and produced a persistent froth when shaken. The whole of the watery extract was dried to a paste and extracted with rectified spirit, filtered and evaporated. This was now extracted with chloroform. The residue was a bitter principle, preserved for test (*Residue No. 1*). The solution of the extract was filtered and evaporated. Some of it was preserved for tests (*Residue No. 2*). It was then boiled in 1 per cent. sulphuric acid, which left a dark green resinous residue, and a clear solution above. It was filtered and both preserved for tests (*Residue No. 3*), and (*Fluid No. 2*).

The various residues and fluids thus obtained were then tested to determine whether they contained alkaloids, glucosides or resins.

Tests.—Fluids Nos. 1 and 2 gave a precipitate with mercury perchloride, picric acid, tannic acid, iodine solution, phosphomolybdic acid, phosphotungstic acid, mercury potassium iodide (Dragendorff's reagent). A control was kept with 1 per cent. sulphuric acid and with 1 in 1,000 of quinine sulphate, which gave corresponding precipitates. It also gave a Prussian blue reaction when fused with sodium and treated with ferrous sulphate and acidified with hydrochloric acid (test for nitrogen). It gave no colour reactions, probably due to impurities.

Residue No. 1 was a bitter principle, soluble in water and alcohol, less so in chloroform. It reduced Fehling's solution to some extent, but copiously so when hydrolysed with 1 per cent. sulphuric acid.

Residue No. 2 was insoluble in water, soluble in alcohol and chloroform, greenish in colour, and when tasted it gave a pricking sensation.

Residue No. 3 was a dark green resinous substance, colourless, and when heated to 100°C. it becomes semi-solid. It dissolves in alkalis and in alcohol, but is insoluble in water and acids.

It appears from the above tests that *Centropeda orbicularis* contains:—

- (1) An alkaloid.
- (2) A soluble glucoside.
- (3) Traces of saponin.

Of the above total contents probably the active element is the alkaloid, inasmuch as a watery solution kept for over three months was found pharmacologically active a period sufficient to decompose glucosides and saponins.

PHARMACOLOGY.

Heart.—A frog's heart was perfused with R/10 Ringer's solution (i.e., NaCl 0.6 per cent., KCl 0.03 per cent., calcium chloride 0.0025 per cent., *vide* Burridge, at 19°C. with the usual result of a diminution of contraction within half an hour.

Next at D₂ the watery extract in R/10 at pH 10 was perfused. A gradual rise in contraction followed, as shown in tracing 1B. The strength was successively increased with the result that the maximum contraction was attained at D₂. It was maintained at practically the same level till the strength was increased to D₆. At D₇ it began to show positive signs of heart block, ventricular contraction nearly disappeared, followed by complete stopping (Fig. 1D).

The heart was washed out with R/10. Normal rhythm was restored.

From the above observation we could not but come to the conclusion that *Centropeda orbicularis* has a distinct action on the frog's heart, stimulating it by increasing the force of the contractions, and prolonging its systole. In larger doses it has a poisonous action as shown by its causing final heart block.

SUMMARY.

- (1) *C. orbicularis* contains an alkaloid, a glucoside, and traces of saponin.
- (2) It increases the force of contraction of heart, prolongs the systole, and causes heart block in larger doses.

Fig. 1.—Mediastinal tumour: before treatment.

Fig. 2.—Mediastinal tumour: after treatment.

THE EFFECT OF RADIATION THERAPY UPON MEDIASTINAL TUMOURS.

By SUBODH MITRA, M.D. (Berlin), M.B. (Cal.),
F.R.C.S. (Edin.),

Superintendent, Chittaranjan Seva Sadan, Calcutta.

MEDIASTINAL tumours belong to a rare variety of disease and the result of treatment is very unsatisfactory. These tumours can be classified according to whether they are radio-sensitive and radio-resistant.

(a) Radio-sensitive mediastinal tumours are:

1. Lympho-granuloma.
2. Lymphosarcoma.
3. Carcinoma.
4. Intrathoracic goitre.
5. Thymus hyperplasia.
6. Malignant metastatic growths.

(b) Radio-resistant tumours are:—

1. Teratoma.
2. Lipoma.
3. Fibroma.
4. Neuroma.

Ross of the Brompton Hospital cited 80 cases of mediastinal tumours of which 32 cases were histologically found to be lymphosarcoma, 12 cases other forms of sarcoma, and 10 cases carcinoma. The post-mortem records of the Johns Hopkins Hospital seem to indicate that Hodgkin's disease is by far the commonest tumour of this region. Lindstaedt says that the commonest benign growths appear to be dermoid cysts; 45 cases have been reported in the literature. They have usually been diagnosed in life by rupture into a bronchus and the consequent expectoration of hair, teeth, etc.

Large mediastinal masses due to tuberculosis and syphilis are occasionally observed. Martini in a series of 14 mediastinal tumours, describes 3 syphilitic growths, 2 tuberculous ones, 3 lymphosarcomata, 2 sarcomata of other kinds, 1 carcinoma, 1 hypertrophic thymus, 1 retrosternal thyroid and 1 undiagnosed tumour.

Burnum had 8 cases, of which 6 were lymphosarcoma, 1 probably malignant disease of the thymus, and 1 Hodgkin's disease.

Schaff has collected 70 cases, of which 34 cases were lymphogranuloma, 6 cases sarcoma, 7 cases carcinoma, 3 cases struma malignum, 1 a thymus hyperplasia, and the remaining 20 cases tumours of uncertain diagnosis. Twenty of these 70 patients, i.e., 28.6 per cent., lived more than two years: of these 20 cases, 8 were lymphogranuloma, 3 sarcoma, 1 carcinoma, 2 struma malignum, 1 thymus hyperplasia, and 5 malignant tumours without having any definite differential diagnosis. Sixteen patients, i.e., 23 per cent., lived more than 3 years, of which 5 were lymphogranuloma, 2 sarcoma, 1 carcinoma, 2 struma malignum, 1 thymus hyperplasia, and 5 malignant growths of uncertain origin. Seven patients, i.e., 10 per cent., lived more than 5

years, of which 1 was a lymphogranuloma, 1 a sarcoma, 1 a carcinoma, and 4 malignant tumours of uncertain origin.

Technique of Treatment.—From a review of cases collected by various authors we find that most mediastinal tumours are of malignant origin, and not amenable to surgical interference. Burnum in his series of 8 cases applied only radium treatment and got satisfactory results. The dose used by him was rather a heavy one, varying from 88,055 m.g.h. to 245,992 m.g.h. on several occasions. He used a 3 mm. lead filter and the whole wrapped with gauze 3 inches thick. Radium was applied from different portals and for varying periods.

Schaff's 70 cases were all treated with deep Roentgen therapy with very good results. The filters used in his cases were $\frac{1}{2}$ to 3 mm. Zn. and 1 mm. Al.; F. S. D. varying from 23 to 50 cm., and having a spark-gap of 38 to 42 cm. The dose required for lymphogranuloma cases was $\frac{1}{3}$ to $\frac{1}{2}$ of the skin erythema dose, and for malignant tumours was about 1 S. E. D.

The writer also obtained good results with deep X-ray treatment. He works with the Tropical Stabilivolt apparatus of constant potential type. According to the Seva-Sadan standard as worked out by the writer, the skin erythema dose upon the Indian skin has been obtained within 20 minutes when working with 180 kv., 4 ma. current, 0.5 mm. Cu and 1 mm. Al as filters, 30 cm. skin-target distance and having a portal 10×15 cm.* As will be shown below, the writer's case got deep X-ray exposures from different portals, and the result was quite satisfactory.

Case.—The patient, B. P., aged 30, a male, Hindu, a resident of Hazaribagh, was recommended by Dr. B. C. Ray to come under deep X-ray treatment on 4th December, 1927, for the following condition:—(1) breathlessness on walking, (2) swelling above the clavicle, (3) cough, the duration of all these symptoms being two months.

The general condition of the patient was far from satisfactory. He was of medium size and slender. Examination of the eyes, nose and throat revealed no troubles. No enlarged glands were found in the neck and anterior aspect of the thorax; the face looked flushed. Heart-sounds were clear; the pulse rate was 72 per minute, and equal on both sides. There was no rise of temperature. Immediately above the middle half of the left clavicle could be felt a mass. This was hard in feel, fixed, and continuous with the dullness felt behind the sternum. The dullness extended $2\frac{1}{2}$ inches to the right of the sternum, and 3 inches to the left.

The blood examination by the Wassermann reaction gave negative results, and there was no history of fever.

The case was clinically diagnosed as a lymphosarcomatous growth of the mediastinum.

An X-ray skiagram was taken (Fig. 1). It shows a big growth in the posterior mediastinum extending more to the left side and reaching above the jugular notch. It was found to be pulsating on screen examination.

* Mitra, S. The biological effect of deeply penetrating Roentgen rays upon Indian skin, and its practical application in deep Roentgen therapy. *Calcutta Medical Journal*, March, 1929.

A course of deep Roentgen-ray treatment as shown in the table below was given:—

The X-ray diagnosis and treatment. *Long Island Med. Journ.*, Bd. 20. Ref. *Zentr. d. Radiologie*, 2187.

Date.	Site of application.	Focus tube.	Rn Tube.	M. A.	VOLTAGE.		Filter.	F. S. D.	Time in minutes.
					Ta.	Tb.			
4-12-27	Anterior aspect of chest.	Nil	R1	4	180	173	0.5 mm. Cu. 1 mm. Al	30 cm.	20
5-12-27	Posterior aspect of chest.	Nil	R1	4	180	173	Do.	Do.	20
18-4-27	Left supra-clavicular region.	Yes	R1	4	180	173	Do.	32 cm.	20
21-4-28	Over the back ..	Do.	R1	4	180	173	Do.	30 cm.	20
24-4-28	Anterior aspect of chest.	Do.	R1	4	180	173	Do.	Do.	20

Four months after the first course of treatment, the patient presented himself for examination. There was no breathlessness and no engorgement of the veins of the neck. A second skiagram was taken (Fig. 2). The mediastinal tumour had entirely disappeared, and the left supra-clavicular glands were palpable. A second course of deep X-ray treatment was given as shown in the table. The patient was quite all right for about a year.

Since the beginning of 1929, the difficulty of breathing appeared again, but the patient instead of informing us took treatment from a local doctor. The condition not being improved, he came again to us on 16th February, 1929. He was found in a very bad state; marked dyspnoea was present, the patient not being able even to lie down. There was a swelling in the supra-clavicular region; veins engorged in the neck. The pulse was soft, thin and rapid. An X-ray examination was made. The mediastinal tumour appeared again, and practically the whole of posterior mediastinum was occupied by it. The patient visited another X-ray clinic for treatment, our X-ray machine not being in proper working order. The condition was so precarious that he died within a week.

CONCLUSION.

Mediastinal tumours are amenable to deep X-ray treatment, but as in other malignant cases the patient must always be in touch with the doctor, and the treatment should be repeated at suitable intervals. In this particular case, the patient did not take any further treatment within the last 10 months. Had he presented himself earlier, the case might have been reacted favourably.

THE USE OF A STANDARDISED PREPARATION OF THE TOTAL ALKALOIDS OF KURCHI BARK IN AMOEBIC DYSENTERY.

By AKHIL RANJAN MAJUMDAR, M.D.,

Bengal Medical Service, Teacher of Materia Medica and Physician, Campbell Medical School, Calcutta.

KURCHI bark and kurchi seeds have been reputed drugs in the Indian system of medicine from almost prehistoric days, being mentioned by Charak in nearly 1000 B.C. for the treatment of subacute and chronic dysenteries. Though the alkaloids were isolated as early as 1853 by Haines, and also by R. C. Dutta in the Chemical Department of the Medical College of Bengal in 1880, and whilst recently some of the local drug firms have put up liquid extracts of it for sale on the market, yet it must be admitted that insufficient advantage of its amoebicidal properties was taken until the researches of Acton, Chopra and Knowles during the last two to three years placed its use upon a scientific basis.

Since the publication of a paper on kurchi alkaloids by Chopra, Gupta, David and Ghosh in the *Indian Medical Gazette* in 1927, and also the contribution by Acton and Knowles "On the Dysenteries of India" in 1928, I decided to take up the investigation of this subject in my hospital and to try and find a *cheap and efficient standardised preparation* for general use.

Chopra and his colleagues have shown that the total alkaloids of kurchi are as active as emetine, though probably their action is a little slower, but they have the distinct advantage of being entirely non-irritant, non-depressant, and have no toxic action on the nervous system. Being non-emetic, the drug is capable of oral administration, and the purified alkaloids when given subcutaneously cause much less local pain than does emetine.

Acton and Knowles remark—"The position with regard to kurchi, in fact, is so interesting that further investigations are urgently called for..... There are large supplies of kurchi

available in India, and both it and conessine could be manufactured at a price well below that of emetine. We would like to draw the attention of the big chemical manufacturers in India to this drug."

My own observations began in July 1928. My immediate object was to find an effective preparation for oral administration which could be prepared cheaply and easily dispensed. The bazaar preparations then available were extract kurchi liq.—a more or less watery decoction, and the "Tabloid" of kurchi bark prepared by Messrs. Burroughs, Wellcome & Co. The watery extracts have hardly any reputation approaching that of emetine, and Acton and Knowles rightly remark—"the bazaar liquid extract, prepared from the powdered bark, is quite unstandardised and hardly suitable for use." I soon found out the reason for this.

I had the bazaar samples of Messrs. B. K. Paul, Messrs. Smith Stanistreet & Co., The Union Drug Co., and of Dr. Bose's Laboratory analysed with regard to their alkaloidal content, and the content of total alkaloids was found to vary from 0.214 to 0.128 per cent (Majumdar, 1929). The usual therapeutic dose of this preparation is from 1 to 3 drs. daily, and therefore the patient would receive only from 0.15 to 0.3 gr. of the total alkaloids in 24 hours. Assuming that the kurchi alkaloids are as effective as emetine, this quantity, given to a patient with frequent stools, must be considered to be utterly insufficient for any therapeutical value.

The indigenous method of preparation was also examined. No watery decoction will give a higher alkaloidal content than 0.15 per cent., and therefore such a preparation cannot be expected to have the specific action of the alkaloids, though its large percentage of tannin might exert some beneficial action in cases of chronic bowel disease.

I therefore decided to have a standardised preparation made, containing a definite amount of the active principles. Fortunately, Mr. Surendra Bhushan Sen, M.Sc., Superintendent of the Bengal Chemical and Pharmaceutical Works, came to my assistance. We worked together for some time, until we evolved an alcoholic extract yielding 1 per cent. of total alkaloids, and not more than 0.25 per cent. of tannin. The daily dose of this preparation which I gave was from 6 drs. to 1 oz., containing from 3 to 4 grains of the total alkaloids. Though even double this quantity is well tolerated, I found that 3 to 4 grains daily was sufficient, provided that not too much of it was evacuated in the stool.

My preliminary report on 15 cases treated with this preparation was read before a medical conference in December 1928, and subsequently published in *Advance Therapy* in January 1929. In that report I showed that, not only are the total alkaloids well tolerated when given by the mouth, the results are also quite dependable, and they rank as high as does hypodermic injection of emetine.

A further series of 34 cases, all showing the motile, vegetative forms of *Entamoeba histolytica* in the stools, have since been treated with this preparation of the total alkaloids, between January and November 1929, the drug being administered orally. The results in this series were as follows:—

	Cases.	Deaths.
1. Pure amoebic dysentery ..	23	5
2. Amoebic dysentery, complicated with bacillary dysentery (mostly Flexner bacillus infections) ..	9	4
3. Cases of amoebic dysentery, complicated with pulmonary tuberculosis ..	2	2
TOTALS ..	34	11

Superficially, these results might appear to be bad, but it is necessary to call attention to the type of cases received at the Carmichael Hospital in Calcutta. They are almost exclusively street beggars in an extreme state of poverty, devitalised to an extreme limit, and usually in a condition of advanced cachexia. Many had œdema of the feet on admission, and even ascites, with incessant stools. In such cases the disease must be attacked by vigorous measures, for there is so little margin for the patients to struggle on, and if they sink to a lower level, nothing will be of any use. On account of the incessant stools in such cases I have frequently had to combine binding medicines with the kurchi preparation in order that the latter might not be evacuated too rapidly.

The general lines of treatment adopted were as follows:—

(i) If there were not too many stools, 10 or less in the 24 hours, the patient was given the standardised extract of kurchi, 6 drs., only, divided into three doses, a day. Under this regimen amœbæ disappeared by the fourth or fifth day, and sometimes earlier. The treatment with the preparation was continued uninterruptedly however for 7 to 10 days according to the severity of the infection, and sometimes a second course of treatment was given after an interval of 4 to 7 days.

(ii) If the stools were more frequent than this, some binding medicine had to be alternated with the kurchi preparation, in order to give the latter a chance of being retained for a sufficiently long time. Therefore mist. creta preparata B. P., and kaolin, bismuth carbonate, or bismuth carbonate with tincture of opium, were given according to the frequency of the stools. But at the same time care was taken not to cause constipation too early, before the alkaloids had a sufficient sterilising effect on the amœbæ.

This preparation of kurchi alkaloids has a very bitter taste, though it is in no way nauseating; yet—as with quinine mixture—patients often dislike it on this account. Further, it often produces no binding effect, and watery faecal stools continued although the entamœbæ had disappeared. In such cases, again, binding medicines had to be given to hasten the convalescence.

Medical College of Bengal and to Dr. J. N. Moitra of the Campbell Medical School for having a large part of the bacteriological examinations done in their laboratories, and also to Mr. S. B. Sen, M.Sc., Superintendent of Bengal Chemical and Pharmaceutical Works, for kindly arranging for all analytical work and preparing the different samples used in this investigation. The successful preparations he has already put on the market, having a standardised alkaloidal content.

A PRELIMINARY REPORT ON THE SUITABILITY OF PARIS GREEN AS AN ANOPHELINE LARVICIDE AS APPLIED TO PUNJAB CONDITIONS.

By M. YACOB, M.B., B.S., D.P.H., D.T.M. & H.,
and

K. S. SHAH, M.B., B.S., D.P.H., D.T.M.

(From the Punjab Epidemiological Bureau, Lahore.)

HAVING recently come across an article on "Paris Green as an Anopheline Larvicide" by Sur and Haripada Sarkar in the July 1929 issue of the *Indian Medical Gazette*, we believe perhaps it may be of interest to workers on the subject if we publish the results of our experiments which were carried out under orders of Lieut.-Col. C. A. Gill, I.M.S., the Director of Public Health, Punjab, during the months of July, August and September 1928 for official purposes, with a view to determining the practical and financial feasibility of employing this method of larval destruction on a large scale in the Punjab. The report on the experiments which was submitted in December 1928 is reproduced verbatim as follows:—

In view of the increasing importance of Paris green (copper-aceto-arsenite) as an anopheline larvicide, a series of experiments, both field and laboratory, were carried out with a view to test the efficacy and practicability of the measure, standardising the procedure, and determining the cost per unit area.

It appears that the credit for the discovery that destruction of anophelines can be accomplished by means of dusting poisonous powders upon water belongs to Roubaud(1), who in 1920 successfully used paraform-aldehyde. Barber(2) during his search for a cheaper and more effective poison than paraform-aldehyde used a number of arsenical compounds and finally selected copper-aceto-arsenite on account of its reliability and higher toxicity for anopheline larvæ than that of any other poison tested. Barber, Hackett and others have shown that the

powder is easy and convenient to use after dilution with fine road dust in a strength of 1:100. The diluted powder when sprinkled on the surface of water in the form of a fine spray keeps floating for a considerable time and its particles are easily ingested by the surface feeding larvæ. The anopheline larvæ, being surface feeders, swallow all particles that are small enough to enter their mouths, and according to this author they do so without any regard to their being food or poison. He further asserts that Paris green can be used for any type of breeding place without previous removal of vegetation, while another great advantage is stated to be its comparative harmlessness for all forms of vegetable life and animals including fish, cattle and domestic animals when used as a 1 per cent. mixture. On the other hand Chalam(3) states it has no action whatever on any of the aquatic stages of culicine mosquitoes nor on the eggs and pupæ of anophelines.

Paris green was used successfully on a large scale by Hayne(4) in the United States in 1922, and since 1923 it has been extensively employed as an anopheline larvicide by Kligler and Shapiro(5) in Palestine, Boyd and Davis(6) in Brazil, Tiedeman(7) in the Philippines and by Hackett(8) in Italy. King(9) of the U. S. A. Bureau of Entomology has also carried out experiments by attempting to spray the dust from aeroplanes over large marshy areas. His results are reported to have been uniformly successful. Experiments have also been carried out by Nicholls(10) in Ceylon, and by Dalal and Madan(11) and Chalam(3) in India.

The preparation known as Paris green has been in use for some time in agriculture as an insecticide and is known by a variety of names, e.g., Schweinfurt green, Mitis green, emerald green, imperial green. Chemically it is copper-aceto-arsenite ($3 \text{ Cu H As O}_3 + \text{Cu (C}_2\text{H}_3\text{O}_2)_2$) a double salt of copper-arsenite and copper acetate. Pure Paris green contains 58.56 per cent. arsenious anhydride and as the commercial products vary in their composition, the name Paris green under the Federal Insecticide Act of 1910, U. S. A.(8), is only used for those products which contain a minimum of 50 per cent. arsenious anhydride. It is a microcrystalline powder of emerald green colour. The sample of Paris green 606 D which was used in the experiments detailed below was obtained from Messrs. G. Siegle and Co., Stuttgart, Germany. As the substance is frequently adulterated it was deemed expedient to have it analysed before use for an estimation of its arsenical contents. The analysis was carried out by the Chemist, Public Health Department, Punjab, who reported the sample to contain 57.7 per cent. of arsenious anhydride and the substance to be practically insoluble in water.

Field experiments.

The experiments were carried out in the summer of 1928 during the months of July, August,

and September. The place selected for the experiments was the Mian Mir storm water channel also, called the Chauburji outfall drain, in Lahore. The channel in its course to the River Ravi from Lahore Cantonment passes under the Bari Doab Canal from east to west, and after passing in front of the Punjab Mental Hospital, which is situated close to the canal, continues its course behind the Central Jail, Lahore. The portion of the channel chosen for the experiments after careful measurement was divided into ten sections, each consisting of 108 yards. The sections were demarcated by means of wooden pegs with numbers marked on each.

From 26th July to 8th August, general preliminary larval surveys of the whole channel were made in order to determine the character of the water and nature of the bank in each section, as well as the relative prevalence of anopheline larvæ in the area. It was found that owing to the failure of the monsoon there was no water in sections I, II and III. Sections IV and V contained stagnant water and their banks were overgrown with weeds, long grass and brushwood. Culicine larvæ were plentiful in the sections, but anopheline larvæ were found to vary on an average from 15 to 20 per even ten dips of an enamelled soup dish with a diameter of 10 in.—ten dips having been adopted as the standard for comparing the relative density of larvæ in the various sections. Conditions in section VI, which was used as a control throughout the course of these experiments, were similar to those in section V, but sections VII and VIII were found to have slowly running water in them with 32 larvæ per ten dips. The banks of these sections were again overgrown with grass and weeds, and the surface was covered with leaves and algæ in various places.

Section X had a sullage water drain from the Lahore Central Jail opening into it, and therefore the water in this and the contiguous section No. IX was of a greenish tint with a somewhat offensive odour. As regards aquatic and marginal vegetation in these sections, no attempt was made to remove or alter the natural conditions in any way before the application of Paris green. It may be mentioned here that the anopheline adults bred out from the larvæ obtained from various parts of the channel consisted of *A. subpictus*, *A. culicifacies*, *A. stephensi* and *A. fuliginosus*.

The application of Paris green was started on the 13th August, the procedure adopted being that suggested by Hackett: 1 gramme of Paris green diluted with 99 grammes of fine road dust was used for every 10 square yards of water surface. An abstract of the protocols of some of the tests carried out are given in the attached Table. The results obtained indicate:—

- (1) That an area treated with Paris green remains free of anopheline larvæ until the 3rd day after greening, when very small larvæ again make their appearance.

TABLE.

Number of section.	Type of water.	Banks.	Surface area of water in the section.	Amount of mixture added with date.	Amount of pure Paris green used.	DENSITY OF LARVÆ.				
						Before.	1 day after.	2 days after.	3 days after.	4 days after.
Section IV	Stagnant pool	Overgrown with weeds.	37½ sq. yds.	3,730 grm. on 13-8-28.	37.3 grm.	8 in 10 dips	Nil	Nil	19 in 10 dips	..
Section V	Do.	Do.	Do.	3,730 grm. on 14-8-28.	37.3 grm.	15 in 10 dips	Nil	Nil	10 in 10 dips	33 in 10 dips
Section VI	Do.	Do.	Do.	3,730 grm. on 16-8-28.	37.3 grm.	19 in 10 dips	Nil	Nil	9 in 10 dips	..
Section VII	Slowly flowing	Do.	75 sq. yds.	750 grm. on 17-8-28.	7.5 grm.	32 in 10 dips	Nil	Nil	2 in 10 dips	..
Section VIII	Do.	Do.	540 sq. yds.	5,400 grm. on 17-8-28.	54 grm.	30 in 10 dips	Nil	Nil	95 in 10 dips	95 in 10 dips
Section IX	Stagnant	Do.	Do.	5,400 grm. on 21-8-28.	54 grm.	65 in 10 dips	Nil	Nil	Heavy fall of rain.	..
Section X	Do.	Do.	Do.	5,400 grm. on 22-8-28.	54 grm.	35 in 10 dips	Nil	Nil	Do.	..

- (2) That 1 gramme of Paris green diluted with 99 grammes of road dust is sufficient to destroy all anopheline larvæ in 10 square yards of water surface. Culicine larvæ, leeches, tadpoles, etc., remain unaffected.

A second series of experiments was carried out with 1:200 Paris green road dust mixture. The results obtained show that a little less than 50 per cent. of larvæ are destroyed by this dilution when observations are taken after 24 hours, e.g., in one case 105 larvæ were captured per 10 dips before greening, 24 hours after greening the number of larvæ was found to have been reduced to 47. Consequently it may be deduced that the highest dilution of Paris green compatible with efficiency is 1:100.

Laboratory experiments.

Simultaneously with the field experiments mentioned above a number of laboratory experiments were undertaken to decide:—

- (1) Whether Paris green has any effect on the pupæ of anopheline mosquitoes.
- (2) Whether the eggs of these mosquitoes are in any way affected by Paris green.
- (3) Whether anopheline adults would lay eggs on water that had already been treated with Paris green.

Experiment I.—Ten almost full grown anopheline pupæ were placed in water in each of two enamelled trays under mosquito nets, and 1 per cent. Paris green in the proportion of 100 grammes of the mixture per 10 square yards was dusted on one tray, the other being left as a control. Next day all the pupæ in both trays had hatched out into adult mosquitoes, showing that Paris green had produced no effect on the pupæ. This experiment was repeated three times with similar results.

Experiment II.—Some female anopheline mosquitoes caught from nature were allowed to lay eggs in two enamelled trays of equal surface area containing water. One tray was kept as a control, whilst the other was dusted with 1 per cent. Paris green. The eggs in both trays hatched out into larvæ. But whereas the larvæ in the control tray were active and lively, those of the other were sluggish in their movements and all were found to have been destroyed 24 hours after hatching; the control having remained unaffected. Apparently Paris green has no effect on anopheline eggs.

Experiment III.—Some water was put into two trays of equal surface area. One of them was sprinkled with 1 per cent. Paris green the other was left as a control. Both the trays were placed under one mosquito net and 10 gravid anopheline females introduced into it. After 24 hours it was found that eggs had been laid in both the trays, showing that anopheline females will lay eggs on water irrespective of the fact whether it contains Paris green or not.

Re-application of Paris green and the length of time that should elapse between two treatments.

Since laboratory experiments had indicated that Paris green has little or no effect on anopheline pupæ and that it only affects the anopheline mosquito during the larval stage of its existence, it was essential from the practical standpoint of mosquito control to determine the length of the larval stage under the conditions of temperature prevailing at the time of the ex-

periment. A number of experiments were therefore conducted in trays and jars, but these failed to solve the problem owing to the fact that larval stage was unduly prolonged in the laboratory.

The conditions under which the tests were carried out in the laboratory being far from comparable with those prevailing in nature, it was decided to undertake experiments under conditions as closely approaching nature as possible. For this purpose two borrow-pits of an approximate size of 5 × 3 ft. and 1 ft. deep were prepared on the 2nd September, one in the lawn of the Lahore Medical College and the other on the bank of the Mian Mir storm water channel. Both the pits were filled to the brim with tap water, and immediately covered over with mosquito-netting to prevent mosquitoes from laying their eggs in them. It may not be out of place to mention here that the rainy weather—the months of July and August 1928—had been exceptionally dry with almost total absence of rainfall until the 31st of August when the meteorological conditions suddenly changed and heavy showers took place all over the Province. The temperature and humidity factors which until then had been unfavourable for mosquito-breeding having approached the normal level, it was decided to commence observations on the 2nd September. Gravid anopheline females were allowed to lay eggs in the laboratory. In 24 hours the eggs had hatched out into larvæ and the new born larvæ were transferred to the two pits mentioned above. Observations were continued till the end of September and it was found that it took 7 days for the larvæ to develop into pupæ. The experiment was repeated twice and the length of the larval stage was found to be again 7 days on one occasion and 8 days on the other. During this period the mean maximum temperature was 95.9°F., and the mean minimum temperature 73.7°F.

It is thus clear that under optimum conditions of temperature such as are usually obtainable towards the beginning of autumn the minimum period of larval development varies from 7 to 8 days. It also follows as a corollary to the above that the interval between two applications of Paris green under the same conditions should not exceed 6 days.

Effect of Paris green on very young larvæ.

An experiment was arranged to ascertain whether 1 per cent. Paris green has any effect on very young anopheline larvæ—one day old. Gravid anopheline females were allowed to lay eggs in the laboratory which hatched out into larvæ. These larvæ were placed into two zinc tubs of equal surface area—usually within six hours of hatching—and 1 per cent. Paris green road dust mixture was sprayed on the surface of the water contained in one of these tubs. The other was left as a control. It was observed that almost all the larvæ were destroyed in six hours in the treated tub, the control remaining

unaffected. The experiment was repeated thrice with similar results, thus indicating that 1 per cent. Paris green when sprinkled over water containing very young larvæ in a limited space is capable of destroying them.

During the course of the earlier experiments in the Mian Mir storm water channel the Paris green road dust mixture was usually sprayed on the entire surface of any one section of the channel selected for experimentation. As it is well known that mosquito larvæ are usually found in much larger numbers along the banks under cover of over hanging grass and vegetation, it was decided to carry out a series of observations to determine the relative density of anopheline larvæ at various distances from the bank of the channel. The channel was 15 feet wide and the average of a series of observations is shown as follows:—

Distance from the bank.			No. of larvæ per dip.
Along the bank	13
1 ft.	5
2 "	4
3 "	3
4 "	1
5 "	Nil.
6 "	
7 "	
8 "	
9 "	
10 "	1
11 "	1
12 "	3
13 "	11
14 "	9
15 " (opposite bank)	

It would appear from the above results that the maximum density of the larvæ was found just along the bank, and that it decreased rapidly in proportion as the distance between the bank and the centre of the stream decreased. For all ordinary purposes, however larvæ were usually found up to a distance of 5 ft. from the bank. This was of great practical importance, since considerable saving in time and money could be made by concentrating along the banks of the water course and using Paris green only up to a distance of 6 ft. from the margins so as to be on the safe side. The rest of the stream including its central portion could be safely neglected provided it were free from vegetation.

Technique of using Paris green.

The apparatus used in the field experiments was obtained from Signor A. Missiroli, Stazione Sperimentale Per La Lotta Anti-malarica, Roma, Italy. It consisted of a screener, a mixer, a hand-blower, and a knapsack-blower.

Dilution of Paris green.

For the purpose of these experiments ordinary road dust was collected and sifted through the screener which consisted of a wooden box supported on an iron frame. The box had a hole at the top, a hole at the bottom and a handle on one side. The inside of the box contained a fine sieve. Road dust was introduced from the top and the handle was turned, when finely sifted

homogeneous dust emerged from below which was collected in a container and stored.

Mixing.—The mixing was done by means of the mixer. This consisted of a square box to which handles had been attached on either side so that it could be held by two men and rotated easily. For purposes of convenience and uniformity in mixing, one hundred rotations of the mixer were fixed as the standard.

Distribution.—In a few preliminary experiments distribution by hand was tried, but was found to be unsuitable as a considerable amount of the dust was wasted. The hand-blower was tried next and it was found that it gave an even spread of the Paris green film and prevented waste by automatically measuring the quantity of the dust applied. The hand-blower is very suitable for dealing with small areas, but for water with large surface areas the knapsack-blower is preferable since it dispenses with the necessity of frequently filling up the container, which is the case when the hand-blower is used; thus effecting considerable economy in the time spent in distribution.

Quantity.—As regards quantity it was found that on an average two blows of the hand-blower were required for every square yard of water surface, and that approximately 5 grammes of the Paris green road dust mixture were ejected at one stroke or blow, i.e., 10 grammes of the mixture were distributed per square yard of water surface. In other words 1 gramme of pure Paris green was used for every 10 square yards. In the case of the knapsack-blower it was found that approximately double the quantity, i.e., about 10 grammes, was ejected at one stroke of the blower and consequently only one stroke was required per square yard of water surface.

Cost.—As already stated, all the prophylactic material or apparatus used in these experiments was obtained from Italy, and the total cost including duty, wharfage fees, clearing and landing charges amounted to Rs. 202-7-0 at Lahore. The total cost of 21 kilogrammes of Paris green including duty came up to about Rs. 42-0-0. As 10 grammes of pure Paris green is required for 100 square yards of water surface, the cost for an area of this size would be 4 pies, and for an area of 1,000 square yards about 3¼ annas. For collecting the road dust, sifting it and spraying the Paris green road dust mixture on the surface of water a coolie was employed on a pay of Rs. 15 per mensem.

SUMMARY.

(1) Roubaud discovered in 1920 that anopheline larvæ being surface feeders could be destroyed by dusting poisonous powders upon water, and used paraform-aldehyde for the purpose. Barber in 1921 used a number of arsenical preparations and finally selected copper-aceto-arsenite. Hackett and others have recently employed it in Europe, America, Palestine, Brazil, etc., for anopheline control.

(2) Copper-aceto-arsenite is also known as Paris green, Schweinfurt green and by variety of other trade names. The sample used in the experiments was obtained from Messrs. G. Siegle and Co., Stuttgart, Germany, and on analysis was found to contain 57.7 per cent. arsenious anhydride.

(3) The field experiments conducted during the months of July, August and September 1928 indicate:—

(a) That an area treated with Paris green remains free of anopheline larvæ until the 3rd day after greening, when very young larvæ make their appearance.

(b) That 1 gramme of Paris green diluted with 99 grammes of road dust—1 per cent. dilution—is sufficient to destroy all anopheline larvæ in 10 square yards of water surface in 24 hours. Culicine larvæ, leeches, tadpoles, etc., remain unaffected.

(c) That 0.5 per cent. Paris green is only capable of destroying a little less than 50 per cent. larvæ in 24 hours.

Therefore, the highest dilution of Paris green compatible with efficiency is 1 per cent. when 100 grammes of this dilution are spread over 10 square yards of water surface.

(4) The laboratory experiments indicate:—

(a) That Paris green does not affect the egg and pupal stages of anopheline mosquitoes.

(b) The Paris green film would not prevent anopheline mosquitoes from laying eggs.

(5) Field experiments indicate that under optimum conditions of temperature, such as usually prevail in the Punjab towards the beginning of autumn, the minimum period of larval development varies from 7 to 8 days. Hence the interval between greening should not exceed 6 days.

(6) Very young anopheline larvæ are as susceptible to the action of Paris green as older ones.

(7) The technique of using Paris green is described in detail.

(8) On an average two blows of the hand-blower employed in these experiments are required for every square yard of water surface. In the case of the knapsack-blower, double the quantity is ejected at one stroke, hence only one stroke per square yard of surface is required.

(9) Paris green is fairly cheap. An area of 1,000 square yards costs only $3\frac{1}{4}$ annas for one application. This is exclusive of the operating charges.

ACKNOWLEDGMENTS.

We have great pleasure in acknowledging our gratitude to Lieut.-Col. C. A. Gill, I.M.S., Director of Public Health, Punjab, for initiating the experiments and for his guidance throughout their course. We are indebted to Major R. C. Malhotra, O.B.E., I.M.S., Assistant Director of

Public Health, Punjab (Technical), Epidemiology and to Dr. R. B. Lal, D.P.H., Epidemiologist to the Government of Punjab for many useful suggestions.

Acknowledgment is also due to Mr. Bashir Ahmed, M.Sc., Officiating Public Health Chemist, for the analysis of Paris green.

CORRIGENDUM.

On p. 691 of our issue for December, 1929, in connection with the article by Major Labernadie and Dr. Andre Zeganadin on the use of a tuberculous methylic antigen in the treatment of external tuberculosis, in the first line of the fourth paragraph, the phrase "(not methylic)" should be deleted. Methylic antigen is used throughout; at first diluted as stated; later in undiluted form. We much regret the mistake.—EDITOR, I. M. G.

A Mirror of Hospital Practice.

A SIMPLE TREATMENT FOR NAGA SORES.

By SATYA KINKAR BISWAS, I.M.P.,

Kerkend (Jharria Coal-field), P. O. Kusunda.

NAGA sores are common in Assam as we know from published reports. I find many such cases in this locality during the latter part of the rains. The determining cause is generally some scratch or minor wound, which develops in a few days into a foul, sloughing, deep-burrowed ulcer with profuse discharge. The greyish spongy slough is adherent to the surface and is difficult to remove. Dressings with the usual antiseptics can be applied for weeks without cure. I have found the following form of treatment, which is cheap, very satisfactory.

The ulcer and the surrounding parts are cleaned with soap and warm water. The skin around the ulcer is smeared thickly with vaseline and then pure carbolic acid (phenol) is applied to the ulcer with a cotton swab. The acid must come in contact with the entire surface of the ulcer. The excess of acid is dried up with a piece of cotton-wool. The procedure, though apparently drastic, does not cause much pain.

The smarting pain remains only for a few seconds. After this, a piece of lint with sterile vaseline is put on the ulcer and covered with usual dressings. Thereafter the ulcer is dressed daily antiseptically. In almost all cases the cure is effected in a week or so, but, should the slough reappear, a second application by the same procedure is sure to bring about a cure.

A CASE OF GEMINATION OF TEETH.

By P. S. KHOSLA, M.B., B.S. (Punjab), L.D.S. (Edin.),
State Dental Surgeon, Civil Hospital, Jammu, Tawi.

GEMINATION is a developmental fusion of teeth or denticles, partially or completely preserving the outline of the constituents.

The condition was noticed in a Hindu male aged about 22 years. As will be seen from the figure of the cast of the lower jaw given below, the fusion is practically complete in this case. The line of fusion is but faintly marked and is indicated by an arrow in the figure, the teeth affected being the left central and lateral incisors of the lower permanent set.

The peculiarity about the case is that gemination appears in the permanent set of teeth, which is a rare thing, it being more common in the case of the deciduous teeth.

The real explanation of the condition is not well known, but it is said to be either an example of atavism, the shortening of the jaws of animals in the process of evolution being concurrent with the appearance of complicated teeth, the result of fusion of two or more normal tooth-germs or of a tooth-germ and a supernumerary tooth-germ, or a result of dichotomy or bifurcation of tooth-germs.

A CASE OF JARISCH HERXHEIMER PHENOMENON.

By R. C. MAHAJAN,

District Medical Officer, G. I. P. Railway, Sholapur.

I CAME across the undermentioned case in my routine examination of the Railway candidates. I reproduce part of the notes I submitted to the

Principal Medical and Health Officer, on this case.

An Anglo-Indian, male, 32 years of age, of good physique and working as fireman.

(a) Previous History.—

(1) History of venereal sore (diagnosed to be syphilis).

(2) History of unconsciousness, accompanied by stertorous breathing and loss of control over the sphincters, lasting for a period of 72 hours, after the second injection of 0.45 gms. of Neosalvarsan in February 1929.

(3) On regaining consciousness he noticed a helpless left arm and leg and a distorted right face.

(b) Present Condition, July 1929.—

(1) The left leg and arm are spastic and rigid. Atrophy or loss of nutrition are not very noticeable. The grip is, however, weak.

(2) The left knee-jerk and ankle clonus are markedly exaggerated, Babinsk's sign present. Upper limb jerks exaggerated. No loss of epicritic or protopathic sensation.

(3) Slight paresis of right face, unequal contraction of pupils, right pupil sluggish in response to both light and accommodation.

CONCLUSION.

From the above it is clear that it is a case of Jarisch Herxheimer phenomenon, following a Neosalvarsan injection. Harrison states these cases are very rare. I have shown this case to the Medical Association of Sholapur, and no practitioner seems to have come across such a case before. The special features of this case are:—

(1) The patient is a comparatively young man, aged 32.

(2) The phenomenon has supervened on the second injection.

My grateful thanks are due to Dr. P. L. Stallard, Principal Medical and Health Officer, G. I. P. Railway, for kind permission to publish this case.

A CASE OF DENTIGEROUS CYST. (FOLLICULAR ODONTOME.)

By COLIN McIVER, M.R.C.S., L.R.C.P., D.T.M. & H.,

MAJOR, I.M.S.,

Superintendent,

and

NISANATH GHOSH, M.B.,

Radiologist, Berry-White Medical School, Dibrugarh, Assam.

THE accompanying photograph shows the face of a young girl with a tumour of the upper jaw

obvious exciting cause. The rate of growth was not very rapid. The patient came before us on 19th September, 1928.

Condition on arrival:—

(a) *Local*.—A hard, solid, non-fluctuating tumour with a broad base and obviously fixed to the underlying bone. There was no pain, no tenderness, no heat, no change in superjacent skin, no change in neighbouring lymph glands and no discharge from the nose. The mass projecting inside the mouth at the alveolar margin and the palate was slightly depressed. There was no carious tooth but there was irregularity in the line of the teeth. As the subject was very young it could not be made out with certainty if any permanent tooth was really missing or not.

(b) *General*.—A young girl of fair health aged about 11 years.

(c) *Radiological*.—X-ray examination of the part showed two misplaced teeth, both lying almost horizontally (see x-ray photograph).

Points of interest in this case are:—

(1) Occurrence in the upper jaw—an

which proved to be a dentigerous cyst, but at first sight was rather unlike it. The details of the case are as follows:—

History.—The history was of several years duration. The onset was insidious and without

uncommon site for dentigerous cyst, the lower jaw being the usual site.

(2) Establishment of diagnosis by horizontally misplaced teeth discovered by x-rays.

(3) First sight resemblance to sarcoma.

Indian Medical Gazette.

FEBRUARY.

THE CHOLERA BACTERIOPHAGE.

THE annual all-India Conference of Medical Research Workers, held in December under the auspices of the Indian Research Fund Association at Calcutta, has now come to be an important function; the Conference in 1929 indeed was attended by 53 delegates from the Government of India and provincial governments and four visitors. At this Conference the most important discussion centred around the present position and future work on the subject of bacteriophage, especially in relation to cholera, and the results are of such interest and importance that we hope that a summary of them may be of interest to our readers.

As Dr. Bentley was careful to explain, the eyes of the world are on India, and on Bengal in particular, with regard to the question of cholera control, for when pandemics originate in Eastern Bengal and do not subside until they reach the Mississippi, public health authorities in countries outside India are apt to take a serious view of the situation, and to call upon India to take measures to control the disease within her borders. That control, Dr. Bentley claimed, can only be affected by wholesale inoculation and a close study of the epidemiology of the disease. In the forthcoming financial year, however, the Indian Research Fund Association has set aside a large sum of money as a provisional measure for the study of the epidemiology of cholera in certain areas, and is advertising for the services of a competent bacteriologist to investigate epidemiological conditions in these areas. The Jharia mines area is one of these which is under very extensive sanitary control and in which detailed information with regard to the population is easily available, it is therefore particularly suited to such an investigation.

Cholera, in brief, is perhaps the most dominant medical research question in India to-day. The 1928 Conference passed the following resolution on this subject:—

"This conference of medical research workers recommends that the whole question of the epidemiology of cholera should form the subject of an enquiry under the direction of a first class expert."

Such a commission can only be built up by degrees, as funds and workers become available, but the work in this direction on cholera bacteriophage is so important that it deserves the widest publicity. A whole morning at the Conference was given to discussing it.

The first speaker was Dr. Igor N. Asheshov, who has taken Dr. d'Herelle's place, and is

working under the Indian Research Fund Association at Patna. Dr. Asheshov has had the great privilege of working in collaboration with Dr. d'Herelle for several years, and has been studying the 'phage for some nine years. He claims, with d'Herelle, that the 'phage is an ultra-minute and living organism, as it can be cultivated and sub-cultivated from tube to tube, just as are the bacteria upon which it feeds. In testing cholera bacteriophages, he has found that there are three strains of 'phage which may be termed A, B and C. Neither A, B nor C 'phage will by themselves, nor will a combination of any two of them, completely lyse a culture of the cholera vibrio on an agar plate; after the initial lysis a "secondary growth" is obtained which consists of vibrios which have acquired a resistance to the strain or strains of 'phage used. When all three 'phages are mixed, however, there is complete lysis, and no secondary growth appears. Experiments with strains of the cholera vibrio from different parts of India would appear to indicate that there are several different antigenic races of this organism—three at least; whilst with regard to the 'phage against dysentery bacilli at least five, and possibly more, different antigenic strains are evident.

By an extremely ingenious line of research work, Dr. Asheshov has been able to determine in any one instance which type of secondary vibrio he is dealing with. Thus type A bacteriophage will destroy the secondary organism which has resisted the action of B and C bacteriophages; type B bacteriophage will destroy an organism which has resisted the action of A and C bacteriophages. This raises the expectation that in any given outbreak the type of primary and secondary vibrios present may be rapidly determined, and also the type or types of bacteriophage needed best to deal with them. Enumerative methods have also been worked out by which it is possible to estimate the strength of a bacteriophage solution in terms of its lytic action on a standard broth culture, using serial dilutions of the bacteriophage, as in carrying out a Widal reaction.

To be effective, therefore, cholera bacteriophage should contain all three elements of types A, B and C. Of these A has the most rapid action, but is unfortunately the most unstable. Types B and C act more slowly, but are much more stable. It is as yet too early to report large scale results, but the 'phage was tried in connection with the annual pilgrimage at Puri in 1929. The results were as follows:—

(a) In the treatment of actual cases of cholera at the Puri hospital results were disappointing. It was only subsequently discovered that the 'phage has these three elements A, B and C, and that the A element is unstable. The difference in antigenic power of the strains of cholera vibrio imported into Puri from different places all over India became apparent on laboratory studies.

(b) In a circumscribed area in the centre of the town, around the main temple, all wells were treated with bacteriophage, and no other measure—the usual measures of treating the wells with permanganate or chlorination being suspended. The incidence of cholera within the protected area was one-tenth of that in the unprotected area.

Once the importance of the A 'phage was realised, further clinical experiments were tried out at Patna Medical College Hospital. Here results were not satisfactory until the whole control and nursing of the patients was taken over by the members of the staff of the enquiry. After this results were extremely satisfactory, the mortality being considerably reduced.

It was found, however, that treatment with saline and alkaline infusions had to be continued; also all bedpans should be sterilised. No anti-septics should be administered whilst the 'phage is being given orally, as they may kill off the 'phage more rapidly than the causative organisms of the disease.

Briefly, the present position reached by Dr. Asheshov's enquiry is that:—

(i) The A type of 'phage is so unstable and delicate that some method of rendering it more stable should be evolved. This has already been partially realised.

(ii) The three essentials which have to be realised if the 'phage method of prophylaxis and treatment are to be successful are that (a) the bacteriophage must be polyvalent against all strains of the true cholera vibrio; (b) it must be rapid in action, producing complete and permanent lysis within two hours; and (c) it must be stable and must retain its activity for at least four to six months under tropical conditions.

It will be seen that Dr. Asheshov's work, whilst of basic and fundamental character, is yet—rightly—directed towards discovering the basic principles underlying the action of bacteriophages, and that so far the application of bacteriophage in the field is still experimental.

Dr. Asheshov's introductory address was followed by a report by Lieut.-Col. J. Morison, I.M.S., Director, King Edward VII Memorial Pasteur Institute, Shillong, on the use of bacteriophage under field conditions. Here no attempt has been made to isolate different strains of 'phage, and a general mixture of strains of both cholera and dysentery 'phages has been used, the idea being to produce a polyvalent remedy. Details with regard to preparation of this bacteriophage are given in a paper in the July 1929 issue of the *Indian Journal of Medical Research*. The polyvalent bacteriophage has been very widely issued throughout Assam during 1929, over 127 litres being indented for. Circular letters and a standardised form of report on results have been issued to tea garden doctors, asking for reports, and these are being collected for analysis and publication. Results with the 'phage in cases of bacillary dysentery have been almost uniformly good. As a prophylactic, 'phage was

tried in one of the Assam jails; of 192 prisoners who received 'phage, 5 developed dysentery; of 169 controls who did not, 28 developed dysentery. In three small localised epidemics of cholera in Shillong, Goalpara, and Salmara 57 cases were treated with 'phage with 15 deaths—mortality 26 per cent.; in the control 92 cases who received no 'phage there were 50 deaths—mortality 54 per cent. In a local outbreak in Jakreni village in the Khasi Hills near Shillong,* results were as follows:—

	Cases.	Deaths.	Mortality.
<i>General, during the epidemic—</i>			
Without bacteriophage	78	63	80.8 per cent.
Receiving bacteriophage	65	7	10.8 "
<i>Cases falling ill after bacteriophage became available—</i>			
Without bacteriophage	13	12	..
Receiving bacteriophage	59	7	..

Thanks to Col. Morison's energy, bacteriophage treatment and prophylaxis has become almost the rule in bacillary dysentery and cholera outbreaks in the tea gardens in Assam, and it will be of very great interest to study the results.

The third speaker at the discussion was Lieut.-Col. J. Taylor, D.S.O., I.M.S., Director, Pasteur Institute of Burma, Rangoon. Colonel Taylor reported that he had had no opportunity of testing 'phage under epidemic conditions, but he had especially investigated the results with and without 'phage treatment in sporadic cases of bacillary dysentery and cholera. In such cholera cases the 'phage treatment had not improved results as compared with controls, and there had been but little evidence of the development of bacteriophage in convalescent patients. d'Herelle has attributed the natural decline of an epidemic to the development of bacteriophage in the affected individuals and even in the environment, but the results in Rangoon did not support this claim. They applied, however, to sporadic cases, and not to epidemic conditions. Therapeutic administration of the 'phage in cases of bacillary dysentery did not appear to have assisted in recovery, as compared with the control cases.

Major R. H. Malone, I.M.S., reported that he had been investigating the presence or absence of bacteriophage in flies and in well waters in relation to the presence or absence of cholera in villages in the Punjab. Up to date results were inconclusive, though a potent cholera bacteriophage had been found in both flies and wells.

* We hope to publish Col. Morison's report on this outbreak in our next issue.

It remains to take stock of the present position. It was unanimously agreed that the three major enquiries should be continued during the next financial year, and that Dr. Asheshov's investigation was of fundamental importance. At present we are so ignorant with regard to bacteriophage that investigation of the fundamental biological principles underlying its use and action are essential. Further trial in the field is also indicated. Its administration is simplicity itself; it is administered orally, preferably on an empty stomach, and no antiseptics should be given orally beforehand or subsequently. Dr. Asheshov proposes now to replace the ampoules in which phage was previously sent out by ordinary medicine bottles, fitted with a cork, traversed by a fine capillary glass tube. The bottle having been sterilised, it is filled by vacuum pressure with the phage solution through the capillary tube, which is then sealed, and the cork sealed up with melted paraffin wax. In this way a large supply, suitable for repeated administration to individual patients, or for large scale prophylactic use, is readily available. If cholera is at the moment India's greatest public health problem, it will be seen that research work with regard to it is far from being neglected, whilst the summaries of annual reports elsewhere in our columns show that the public health aspect of the subject is also being very closely attended to.

SPECIAL ARTICLE.

A REVIEW OF OUR PRESENT KNOWLEDGE OF THE BACTERIOLOGY AND PATHOLOGY OF HUMAN LEPROSY.

By JOHN M. HENDERSON, M.B., Ch.B. (Glasgow),
Working under the British Empire Leprosy Relief
Association at the School of Tropical Medicine and
Hygiene, Calcutta.

Introductory.—The purpose of this paper is to indicate in outline the salient features of the bacteriology and pathology of human leprosy in the hope that the bird's-eye view so obtained may result in the clarification of the ideas of the author, and, we trust, of other workers in the same field, and that fresh avenues of approach to this difficult problem may suggest themselves. There are certain aspects of the subject to which we shall devote merely incidental reference, not, let us hasten to add, because we have the impertinence to arbitrate on the validity or otherwise of any or all of the observations comprehended in the particular aspect or aspects in question, but merely because the observations have not received that unanimous confirmation which is a necessary condition to their acceptance as scientific facts. Such important but still highly controversial topics as the cultivability of the organism of human leprosy, the rôle of insect vectors in the spread of the disease, the transmission (successful or otherwise) of human leprosy to lower animals, and the relationship of human leprosy to rat leprosy, will so far as possible be omitted from the present discussion. That there is at times a lamentable lack of unanimity of opinion even in those aspects of the subject to which we shall confine ourselves, will, we fear, become only too obvious to the reader. This is doubtless unfortunate, but the authorities quoted are such that due regard must be paid to their (at times

divergent) findings. Any other plan would, we feel certain, result in the degradation of this conspectus to the level of an ill-timed expression of personal opinion. The plan that we have followed is to condense each section of the subject as far as possible and to give in the appropriate section of the bibliography a full list of references so that those interested in particular aspects may be provided with a large number of original sources.

Bacteriology.

There is a general consensus of opinion that human leprosy is due to the organism first described by Armauer Hansen in 1871 and now called *Mycobacterium lepra* (Hansen), or, more familiarly, "the leprosy bacillus" or "Hansen's bacillus." The well-grounded belief in this organism as the cause of leprosy depends on the repeated observation by workers all over the world of its presence in greater or smaller number in all leprosy lesions. Final proof by animal inoculation with the production of lesions in all respects similar in course and in histological appearances to those occurring naturally in man is still, however, lacking.

The type morphology of the organism is that of a uniformly stained rod, straight or slightly curved, varying in length from 1.5 to 6.0 μ and in breadth from 0.2 to 0.45 μ . In highly positive lesions the organisms are present in very great numbers and they show a distinct tendency to be arranged in bundles of greater or smaller size; in weakly positive lesions this feature is not present.

Variations from the type morphology are frequently met with; in general these fall under three main heads, and they may occur either singly or in combination. (a) The organism may show a fragmented appearance with unstained gaps throughout its length. (b) Deeply staining particles, varying in size, number and position may occur in the bacillary protoplasm. The word "spore" is sometimes used with reference to these deeply staining inclusions—without any adequate justification in the present state of knowledge. (c) The organism may manifest alterations of different degrees in its characteristic acid-fast property, combined not infrequently with departures from the type bacillary form.

The significance of these aberrant forms is not certainly known, but there is a general impression that they occur most commonly and in relatively greatest numbers in patients who are passing from the infective to the non-infective stage of leprosy, and that the appearance of unstained zones in the body of the organism represents the first stage in a degenerative direction.

Cardinal features of *M. lepra*.—The organism of human leprosy has five cardinal features. (1) It is, in general, acid-fast. (2) It grows on artificial culture media with difficulty or, as certain workers maintain, not at all. (3) Its pathogenicity is low. (4) Introduction of this organism to laboratory animals has not so far resulted in the production of progressive lesions at all comparable to those of the naturally acquired human disease. (5) Ordinary methods of examination frequently fail to reveal *M. lepra* in certain types of lesion which are clinically leprotic in nature.

(1) **The acid-fast property of *M. lepra*** is mainly relied on for the recognition of this organism in the tissues, and the well-known Ziehl-Neelsen technique is commonly employed; incidentally the application of heat is not essential. The reason for the acid-fastness of the organism is not known: the property in question is usually referred (somewhat vaguely) to the supposed waxy "coat" or "capsule" possessed by the organism. Wade, however, strongly refutes this view, and believes that the acid-fastness is due to "lipins" which are combined in the bacillary protoplasm with proteins as lipoproteins, and the demonstration of these in the body of the organism has recently been effected by Paldock (1927, 1927a, 1927b). That *M. lepra* shows variations in the degree of resistance to decolorization by mineral acids is an experience common to all leprologists, and this even when a constant technique is employed. In

general, lesions tending to undergo resolution show less resistance to acids on the part of their contained organisms which, therefore, take up more of the counter-stain. Hence one may get red, violet, and blue bacilli in the same preparation. This loss of the acid-fast property is also seen in microscopic preparations which have been kept for some time; the bacilli in these tend to fade rather quickly in a tropical climate, particularly if the mounting media are on the acid side of neutrality.

The majority of workers are in agreement that *M. lepræ* cannot be separated from other members of the acid-fast group by differences in staining properties only. Rudel (1928) however in a recent paper claims that by his method, a modification of the classical Ziehl-Neelsen technique, he can differentiate leprosy from tubercle bacilli. *M. lepræ* is also demonstrable by other methods of staining, but none of these can challenge either in reliability or in ease of application the Ziehl-Neelsen method.

(a) The organism is stainable by the Gram method or one of its modifications, especially if (as shown by Arning and Lewandowsky) the violet stain is allowed to act for forty-eight hours: the organism is Gram-positive.

(b) It is also stainable by osmic acid (a few hours' application), being coloured faint brown; this is Hansen's original method.

(c) Prolonged application of many basic aniline dyes (fuchsin, methyl and gentian violet, methylene blue, vesuvin, nigrosin, aurantia, and malachite green) succeeds in staining the organism, and it is also demonstrable by silver impregnation methods.

(d) Mention should also be made of the staining methods advocated by Unna (1906) mainly because these methods do not appear to have been at all extensively tried out.

(I) Unna's thymen victoria blue-safranin method, by which it is claimed that living organisms stain dark blue-black, and dead reddish-yellow.

(II) Unna's polychrome methylene blue-potassium ferricyanide method whereby a "coccothrix" form of the organism is stated to be capable of demonstration.

As noted above neither of these methods seems to have been tried out at all extensively and it would appear desirable that this should be done. The present author has been using both methods lately—but so far without satisfactory results. The time devoted, however, has been too short for the expression of a definite opinion and this line of work is being continued. It would be advantageous if other workers would pursue the same path so that some sort of collective opinion may be obtained. Neither method from its length is suitable, however, for rapid diagnostic work.

M. lepræ has not so far been demonstrated by intravital staining methods.

(2) *The question of the artificial cultivation of M. lepræ* is one of the most difficult in the whole range of leprosy problems, for in spite of painstaking researches by numerous competent workers this question has still not left the realm of the debatable. It is closely bound up with the allied question of the production of human leprosy in experimental animals and until this latter object has been achieved it would appear difficult to determine whether any given culture is or is not *M. lepræ*. It is not our present purpose to discuss this subject: those interested will find adequate accounts of various aspects in the papers of Kedrowski, Van Houten, Rost, Emite-Weil, Clegg, Duval, Beauchamp Williams, Fraser, Bayon, Currie, Clegg and Hollmann, McCoy, Marchoux and others (see bibliography), as well as in the textbook of Rogers & Muir and in Kolle & Wassermann's *Handbuch der Pathogenen Mikro-organismen*.

(3) *The low pathogenicity of the bacillus of leprosy* is an observation which has been made clinically by all who have studied the disease with care. There is probably no other systemic disease in which the specific organism may be present in such vast numbers without giving rise to much graver general signs and symptoms. It is, we think, a fortunate circumstance that the infectivity of the bacillus of leprosy is also, generally speaking

low; for in any endemic area there are large numbers of "carriers" going about their ordinary avocations without grave discomfort and at the same time disseminating the infection broadcast from the skin and nasal mucous membrane.

Further evidence on this point is available in the mortality statistics of leper asylums and hospitals. Pineda (1924) in his studies at the Cullion Leper Settlement, Philippine Islands, showed that in only 2.3 per cent. of three hundred autopsied cases could leprosy be assigned as the cause of death. In the experience of the Philippine workers tuberculosis and nephritis are the two commonest causes of death in the lepers under their care.

(4) *Animal inoculation*.—The literature on animal inoculation with human leprosy material is nearly as extensive as the literature on the cultivation of the bacillus of leprosy, and a perusal of it leaves the reader with the same feelings of dissatisfaction and dubiety. Results of a kind have been obtained in that proliferation or, as certain sceptical critics have insisted, survival of organisms at the site of inoculation has taken place, but there is no well authenticated instance of the production in any animal of a condition resembling the naturally acquired human disease. A large series of experiments on monkeys, rats, guinea-pigs, Chinese hamsters, Japanese dancing mice and Belgian hares has been in progress at the School of Tropical Medicine and Hygiene, Calcutta, during the past eight years but the results have been in our opinion negative and unworthy of publication. Practically all animal experimental work (including our own) suffers from one serious impediment, namely that the inoculum consists not of the specific organism alone but of the specific organism plus human tissues or tissue juices, resulting obviously in the introduction into the experiment of an unknown factor of possibly large dimensions. The literature on animal inoculation with human leprosy, leprosy material, unsatisfying though it is, is important and I have therefore included in the bibliography a list of the more important and accessible papers.

(5) *Inability to find the specific organism in lesions* which are on clinical grounds considered by competent leprologists to be of truly leprotic origin is one of the most puzzling features of the disease. That such failure should be encountered in the late trophic manifestations of the disease is perhaps not to be wondered at; such lesions are of the nature of scars—they are evidence not of present but of past disease. The problem becomes more complicated, however, when one fails to find the specific organism in lesions which one is accustomed to regard as early manifestations of the disease, e.g., the so-called macules. There is, however, one point to which investigators in general have not paid sufficient attention, viz., the time factor. If, for example, one were to examine a "macule" which had persisted in a stationary condition for a number of years one would be tolerably surprised to find the specific organism—such a lesion is a scar of the disease just as much as the trophic lesions alluded to above. It does not seem to have been fully realized even yet that, as Impey (1895), Muir (1924) and others have insisted, leprosy is a self-limiting disease.

Leaving aside these objections, however, the majority of workers are in agreement that the acid-fast bacillus of leprosy as we know it is very rarely found in leprosy "macules." Two possible explanations suggest themselves; (1) that the specific organism has died out of the lesions by the time one gets an opportunity to make a microscopic examination, and that it would be detected in every macule if one were on the fortunate position of being able to examine serial sections of such a lesion within a few days of its appearance; (2) that the early leprosy lesion is due to a stage (presumably non acid-fast) in the "life cycle" of the organism which has not been made manifest by our present methods of staining.

With a view to gaining insight into the latter possibility the present author has during the past six months examined several hundred sections of early depigmented

patches, using a great variety of staining and impregnation methods with, at the moment, completely negative results. One is of course up against the supreme difficulty of having to rely almost entirely on the necessarily faulty memory of the average out-patient for the interpretation of the word "early."

Pathology.

The initial lesion in leprosy.—The problem of the initial lesion in leprosy is one which even yet cannot be considered settled. Danielssen (quoted by Hansen) stated that he had seen, at the very beginning of the disease "a slight vaso-motor disturbance indicated by a bluish-red reticular appearance, most clearly marked on changes of temperature." Sticker (1897) having found acid-fast bacilli morphologically similar to *M. lepra* in the nasal secretions of 128 cases of leprosy out of a total of 153 examined, concluded that the nasal mucosa is the seat of the primary lesion. The value of this observation has been largely discounted by the later work of McDonald (1903) and of Brinckerhoff & Moore (1909) in Hawaii, and more recently of Wade & Solis (1927) in the Philippines.

In Sticker's original paper there is no accurate account of the clinical condition of each member of the group of patients examined, and it seems probable that his sample was unduly weighted by the inclusion of a large number of advanced nodular cases in whom positive nasal findings are, of course, common. There is, however, one type of case in which the nasal mucosa may be the seat of the primary lesion, namely, the type in which the onset of the disease is of an explosive nature and is heralded by the simultaneous appearance of multiple lesions at different parts of the body surface.

Modern opinion tends to view leprosy as a disease acquired by inoculation through the skin following prolonged and intimate contact with a patient in a highly infectious stage of disease. Muir in particular is emphatic on the importance of resistance-lowering factors (coincident diseases, bad hygienic conditions and lack of exercise) in the propagation of leprosy. The intimate nature of the resistance of the body to disease is bound up with the nature of the life-processes themselves.

The nature of the "specific cell response" in leprosy.—Uncertainty still exists with regard to the exact nature of the cellular response to invasion of the tissues by *M. lepra*. That the cell which can be found proliferating in all active leprotic lesions (and which, having undergone a lipid degeneration and become crammed with *M. lepra* is then denominated the "lepra cell") belongs to the group of macrophages, is recognized by nearly all modern workers. The question of the *origin* of the macrophage cells of the connective tissue is, however, one on which sharp cleavage of opinion exists among cytologists. Briefly there are two schools: (a) those who believe with Mallory (1914), McJunkin (1925a) & Foot (1919) (1925), Sabin, Doan & Cunningham (1925) that the whole or part of this highly phagocytic group of cells is derived from endothelium of vascular or lymphatic origin, and (b) the opposite school of thought led by Aschoff (1924) and Maximov (1928) who deny that the cells of true endothelium can ever have a phagocytic function and who maintain that the macrophages of the subcutaneous tissues are all constituents of the reticulo-endothelial system, or system of histiocytes. The whole question, although interesting from the purely cytological point of view, appears to be somewhat academic from the point of view of leprosy.

The pathology of leprotic skin lesions.—This subject is dealt with at considerable length in various textbooks of skin diseases and in numerous papers; reference to the more salient features is alone required.

(A) The earliest type of skin lesion histologically speaking, is that known among European workers as the *macule*, and among Indian and African workers as the *depigmented patch*. Histologically there is evidence of a mild chronic inflammatory process in the corium, and the cell proliferation incidental to the inflammatory process shows in the earliest cases a predilection for certain sites—the papillae of the corium, the subpapillary and

deep lymphatic plexuses and the areas immediately surrounding the hair follicles, the sweat and sebaceous glands. The cells concerned in the proliferation are mainly of three types: (1) the macrophage (of connective tissue or possibly of endothelial origin); (2) the lymphocyte; (3) the young connective tissue cell or fibroblast. The extent to which each of these cells takes part in the process varies in different cases, but a feature of interest is the comparatively slight response of the tissues to the invasive process. Irregularities of cornification are occasionally noted and an increase in the numbers of "mast" cells is not uncommon. Acid-fast bacilli are rarely found. Partial loss of pigment is a prominent clinical feature when such lesions occur in dark-skinned races and this loss can sometimes be detected by subjecting skin sections to silver impregnation: but the results are rather irregular.

(B) In the next type of skin lesion, representing a transition stage between the macule (or depigmented patch) and the "nodule," there is much greater activity both on the part of the invasive process and of the defence elements of the corium. Microscopically the cell elements are—with one exception—similar to those already noticed in connection with the depigmented patch but the extent of corium involved is much greater. Masses of macrophage, endothelial-like-cells can be seen infiltrating the corium in all directions, but these masses tend to be broken up into more or less isolated foci by circumscribing collections of lymphocytes and young connective tissue cells. The appearances presented therefore are not unlike those seen in non-caseating tuberculous follicles and the similarity is further heightened by the very frequent presence of giant cells in this type of lesion. The introduction of the term "tuberculoid" is unfortunate; that the changes described can occur without the intervention of a secondary tuberculous infection is agreed by all workers whose experience of leprosy is at all extensive. New-formed blood vessels can be detected, and these doubtless account for the erythema which is a prominent clinical feature of such lesions, and for the infrequency with which caseation is encountered. In sections stained by Van Gieson's method or subjected to silver impregnation the degree of young fibrous tissue formation is well brought out. Acid-fast bacteria, although more frequently encountered than in the true macule, are relatively scanty.

(C) The best known and most frequently described lesion of the skin is the *lepromatous nodule*.* The "nodule" may be single or multiple, circumscribed or diffuse—the last mentioned distribution occurs most frequently in the skin of the face and forehead where it gives rise to the so-called leonine facies. Pathologically the "nodule" is evidence of a virulent infection of the skin by *M. lepra*: in early cases it consists of a mass of macrophage cells crammed full of acid-fast bacilli swamping the corium in all directions and leading to extensive obliteration of normal histological landmarks. Hair follicles, sweat and sebaceous glands are destroyed, the epithelium is reduced to a thin layer covering the dense cellular mass, and the papillae of the corium are flattened out. Apart from the thinning-out process the epithelium appears to suffer little change, and bacilli are very rarely detected in it unless it has ulcerated; the strip of corium immediately underlying the epithelium is also relatively unaffected by the bacillary and cell invasion.

The macrophage endothelial-like cell is, in young nodules, the most prominent of the various cell elements, but it has undergone certain radical changes in appearance from those seen in the previously described types of skin lesions. The most obvious change is that practically every cell of this class is now crammed with a felted mass of acid-fast bacteria so that the number of these organisms in a single microscopic field is often uncountable. The nucleus is pushed to one side and the protoplasm has a vacuolated foamy appearance; the

*Many of the lesions defined somewhat loosely as "nodular" are, however, better described as diffuse lepromatous infiltrations.

macrophage cell presenting these appearances is frequently known as the "lepra" cell. In older "nodules" a variable amount of fibrosis is seen, not infrequently in the form of vertical strands from the underlying subcutaneous tissue; pseudo-inyxomatous degeneration may occasionally take place.

(D) *Embolic lesions.*—During the phase of leprous reaction there may occur, either in previously healthy skin or in an area of skin already the seat of a leprous lesion, small hyperæmic foci slightly raised above the general cutaneous surface. Microscopic examination reveals that these lesions are the result of blocking of the fine skin capillaries by small emboli of *M. lepræ*. There occurs a slight degree of blood vessel dilatation in the immediate vicinity together with œdema of the neighbouring connective tissue, proliferation of endothelial-like cells and occasionally slight diapedesis of red blood corpuscles. In favourable cases *M. lepræ* singly or in small clumps may be noted in the endothelium of the blood vessels, lying free in the dilated lymph spaces, or enclosed in endothelial-like cells. These lesions are, as a rule, very transient in duration and may completely disappear in the course of a few days. Where "embolisation" has occurred in a pre-existing lesion, the differentiation from the phase of reaction occurring in that lesion is often impossible.

(E) The end result of the proliferation of leprous granulation tissue in the skin is the formation of fibrous tissue and the production of atrophic skin lesions. The most important of these is the so-called *crushed tissue paper skin*. Clinically the skin is thin, dry, shiny, hairless and lacking in elasticity. Microscopically there are small foci of cellular accumulation separated by dense strands of fibrous tissue with thinning and irregularity of the epithelium, obliteration of hair follicles, sweat and sebaceous glands, and widespread destruction of elastic tissue. Acid-fast bacteria—usually granular degenerating forms—may be present in small numbers: in very old-standing cases, however, they are not infrequently absent.

Any of these types of skin lesion, with the possible exception of the last, may be modified both clinically and pathologically and at any stage in its evolution by the onset of a general systemic disturbance known as the leprous reaction or "lepra fever," a condition to be described in a later section.

The so-called "immune areas" of the body surface.—

Although leprosy may involve any part of the skin surface, there are certain areas which, in the experience of the majority of workers, are less commonly involved than others; such are the hairy scalp, the glans penis, and the palms of the hands and soles of the feet. A search of the literature reveals, however, that contrary to the positive statements of Hansen, Danielssen, Unna and others regarding the almost complete "immunity" of such areas from leprous lesions, positive findings are not uncommon. As early as 1900 Morrow reported a case of nodular leproide of the scalp, while Glück in the same year found lesions of the glans penis in no fewer than ten out of forty patients examined. Rille, in the following year gave a very detailed report of a case of "tuberous leprosy" with lesions of the soles of the feet. Rogers and Muir, while agreeing on the comparative rarity of leprous lesions of the scalp, state that they have found *M. lepræ* in the corium of the palms and soles of the majority of patients suffering from advanced skin leprosy. In a patient of the Albert Victor Leper Hospital, Calcutta, in whom diffuse nodular infiltration of the skin of the forehead was present, the present author detected *M. lepræ* in an apparently healthy portion of skin removed from the scalp over the vertex, while in a recent case at the Leprosy Out-patient Department of the School of Tropical Medicine and Hygiene, Calcutta, a well marked erythematous lesion of the back of the neck was noted to be extending on to the hairy scalp in the occipital region.

Further evidence bearing on the occurrence of definite leprous lesions in one or other of the regions mentioned has been submitted by Robelin (1901), Bjarnhjedinson (1905), Pernet (1905), and more recently by Neff and Snodgrass (1929).

It is probable therefore that leprotic involvement of these regions is more common than had hitherto been supposed.

Leprosy of the nervous system.

(1) *Sensory nerve endings.*—That *M. lepræ* may occur in the fine nerve terminals of the skin, and in the cornea, has been established by the researches of Unna, Lie, Hansen, Babes, and others.

Even where the skin is apparently slightly involved, examination of appropriately stained sections may reveal thickening of the nerve terminals and occasionally the presence of scanty acid-fast bacilli in the perineurium or in the lymphatic channels immediately around the nerve endings.

(2) *Nerve trunks.*—Clinical evidence of involvement of certain nerve trunks is a commonplace of leprosy practice. The nerve trunks most frequently affected are the ulnar, the internal cutaneous of the forearm, and the radial, in the upper extremity, the external peroneal in the lower extremity, and the great auricular, the facial and the supra-orbital in the head. The changes which take place in the nerve trunks are very similar in kind to those in the skin and are frequently co-existent and contemporaneous with the latter. They consist in brief of an insidious production of leprous granulation tissue within the supporting connective tissue sheaths and septa of the nerve, followed by fibrous organization of the granulation tissue with pressure atrophy and sclerosis of the true nerve fibres. In the beginning therefore the clinical picture is that of nerve fibre irritation—hyperæsthesia, tingling and neuralgia, followed by loss of the sensations of pain, superficial touch and temperature discrimination, and terminating in signs and symptoms of constriction and degeneration of nerve fibres, as manifested by muscle atrophy, deformities of digits and the formation of trophic ulcers. The cellular elements taking part in the nerve lesions are very similar to those already noted in connection with the pathology of skin leprosy.

In very early cases Wade and Rodriguez (1927) maintain that there may be no abnormality other than an irregular increase of the connective tissue surrounding the nerve; in well marked cases, however, lymphocytes, macrophage endothelial-like cells, fibroblasts and new formed fibrous tissue can be detected in varying proportions. The occurrence of giant cells in leprotic nerves has been noted by Arning, the present author (Henderson, 1928) and others. As in cutaneous lesions, the clinical signs and symptoms and the microscopic appearances may be altered by the onset of a "leprous reaction." *M. lepræ* when present are found, not only in the macrophage cells of the granulation tissue, but also free in the lymph spaces between the nerve fibres and (according to Hansen) in the cells of Schwann's sheath.

A curious complication of nerve leprosy to which Arning, Glück, Shiota and more recently Muir (1924) and Lowe (1929) have drawn attention is the occurrence of nerve abscesses. In almost every case reported this complication has been found in one or other of the nerves of the upper extremity. (Muir and the author, however, recently saw a patient at the Leprosy Out-patient Department, The School of Tropical Medicine and Hygiene, Calcutta, in whom an abscess was found in the trunk of the posterior auricular nerve; scanty *M. lepræ* were found in the abscess material. This case is, in our experience, distinctly rare). The abscess usually consists of white cheesy semi-solid material containing cellular debris, and occasionally a few degenerated acid-fast bacilli. Lowe is of opinion that the occurrence of this complication is intimately associated with the onset of a "leprous reaction."

(3) *Spinal cord.*—Whether true leprotic changes occur in the spinal cord (and in the ganglia of the posterior roots of spinal nerves) has been a subject of considerable controversy. Soudakewitsch was among the first to demonstrate *M. lepræ* in the spinal ganglia, and his findings were confirmed and amplified by Babes; the latter worker in addition found *M. lepræ* in considerable numbers in the cells of the anterior horn of the spinal

cord on nine occasions in twenty-two autopsies. Positive bacteriological findings in the spinal cord and spinal ganglia have since been reported by numerous workers—Chassiotis, Cotella and Stanziale, Kalindero Lie, Uhlenhuth and Westphal among others, associated in practically every instance with generalized and highly positive leprotic lesions in other organs and tissues of the body.* In pure nerve leprosy (so-called) examination of the spinal cord is usually negative.

The histological changes most commonly found are sclerosis of the posterior columns of the cord, degeneration of the ganglion cells of the anterior and posterior horns, and occasionally bilateral sclerosis of the lateral columns. Jeanselme and Pierre Marie (1898) describe a sclerosis of Goll's column and of the "cornu-marginal triangle" existing with a minimum of alteration in the posterior roots and in Clark's column, which they conclude to be of true leprotic endogenous origin and independent of coincident involvement of nerve trunks. Rogers and Muir on the other hand, while admitting that spinal cord lesions may occur in leprosy, do not consider such lesions to be connected directly with leprosy invasion. They are therefore in agreement with Voit (1900) who declared that whatever degenerative changes are found are due to the chronic cachexia induced by the disease.

(4) *Brain, meninges and cerebro-spinal fluid.*—*M. lepra* have been discovered in the brain in advanced cases of generalized leprosy by numerous authors. Uhlenhuth and Westphal in particular describe and figure the organisms in the cells of Purkinje: the histological changes are usually unimportant. So far as the meninges are concerned there are few characteristic appearances; Doutelepoint and Wolters found *M. lepra* in the pia mater and Brulzer in the dura over the hypophysis cerebri. De Buermann and Guy Laroche have described a localised meningitis with many acid-fast bacilli in the exudate occurring in cases of acute generalized leprosy. In the cerebro-spinal fluid acid-fast bacilli have been detected by Emile-Weil and Tarron and by Jeanselme and Milian.

Major psychoses and psycho-neuroses may occur in association with leprosy, but it is doubtful whether the disease plays any direct part in ætiology. Hansen and Looft described a case of recurrent mania in association with leprosy. De Buermann, Roubinovitch and Gougerot (1906) draw attention to the occurrence of a "psychic toxæmic cerebropathy" in leprosy characterized by antegrade amnesia, defective attention, volition and judgment and in severe cases by hallucinations and systematised delusions.

Bone and joint lesions in leprosy.—Atrophy of bones, particularly the small bones of the hands and feet, first noted (according to Hansen) by Heiberg as occurring in association with leprosy, is frequently seen as an end stage in the disease process. If complicated, as it not infrequently is in the lower extremities, by ulceration of the overlying skin there may occur periostitis with necrosis of bone, sequestrum formation and exfoliation. Hudellet and Moreau (1925) record partial decalcification of the bones of the hand as a constant radiographic finding; this observation they hold to be of value in the diagnosis of early cases. Sawtschenko Doutelepoint and Wolters and Uhlenhuth and Westphal have reported the presence of *M. lepra* in the Haversian canals and in leprosy nodes in the bone substance.

Acute rheumatoid affections of the joints, particularly those of the knee and ankle and the small joints of the hands and fingers with collections of fluid in the joint cavities may occur even at a relatively early stage in the disease. After several attacks of this nature changes in the joint capsule and ligaments may be noted, according to Hansen such joint affections are of the nature of trophoneurotic vaso-motor disturbances.

*The fact that *M. lepra* may be present in relatively large numbers in the circulating blood of advanced "skin" cases, particularly during the phase of reaction should be borne in mind in assessing the value of these observations.

Leprosy of the lymphatic glands.—Involvement of lymphatic glands, particularly the femoral, inguinal, and axillary groups, less commonly those of the anterior triangle of the neck and the epitrochlear gland at the elbow, is a frequent finding in leprosy. The histological appearances and the facility with which acid-fast bacilli can be recovered vary according to the type and stage of the disease, while the former are further complicated by the periodic changes undergone by lymphatic tissue in performing its physiological function of lymphocyte production.

Wade has drawn attention to the frequency with which lymph glands act as reservoirs of *M. lepra* and has further emphasised the fact that the degree of gland involvement does not depend on the extent of coincidentally infected skin in the area drained. The former observation has been further elaborated by Pineda (1927) and the present author (Henderson, 1927). The former worker found *M. lepra* in the femoral glands of 9 out of 53 patients in whom repeated examination of the skin extending over a period of two years had been consistently negative. He also records positive findings on five occasions in eleven autopsies carried out on patients who had been bacteriologically negative on skin examination for periods ranging from five to seventeen months. The present author in an examination of the femoral glands of 93 patients found *M. lepra* on 27 occasions. Simultaneous examination of skin smears gave negative results in 66 out of the total 93, and of the 27 positive gland findings 4 occurred in this negative skin group. Gland puncture only was employed and hence the positive findings are probably on the low side; this is further emphasised by the fact that microscopic examination of an excised gland found negative on puncture a few days previously revealed undoubted *M. lepra* in small numbers.

The frequency with which double infection, usually with tubercle bacilli, may occur in leprotic lymph glands has been remarked by various workers. McCoy (quoted by Muir) found combined infection in the lymph glands on 10 occasions out of a total of 650 examinations. Rogers and Muir record the occurrence of a gland abscess in a patient suffering from leprosy; acid-fast bacilli were found in the pus from the abscess, and this material on inoculation into four monkeys caused fatal miliary tuberculosis in all the animals. The present author (unpublished observation) found on one occasion by microscopic examination a mixed infection of leprosy and filariasis in a lymphatic gland from the groin. It is probable that systematic examination of our patients in India would reveal such a mixed infection not infrequently.

The possibility of leprosy lying latent in lymph nodes prior to declaring itself on the skin surface, in nerve trunks or in the body generally, has been explored by various workers, and in particular by Marchoux (1923). In this connection it is of interest to note that Sorel (1912), examining a group of 15 presumably healthy persons living in contact with leprosy patients, reported positive findings in the lymph glands of 1. Conoy (1914) found *M. lepra* in the "genital ganglia" of the healthy wife of a leper, while Serra (1926) reported positive findings in the lymph glands of all of 12 apparently healthy commensals of lepers.

The special sense organs in leprosy.

(1) *The eye and adnexa.*—Involvement of the eye and its adnexa is not uncommon in leprosy, but the frequency with which eye complications occur differs in the experience of various observers.

Lyder Borthen (1899), studying this question in Norway, found complete blindness in 17 per cent. of 277 lepers examined. Wood (1913) in South Africa records eye involvement in more than 50 per cent. of "anaesthetic" cases and states further that 90 per cent. of "tubercular" cases suffer from eye complications in the first ten years of the disease, and that "nearly all who survive longer are blind."

Hight (1918) found eye lesions in 77 out of 101 Chinese lepers in Siam, while Fernando (1923) in the Philippines noted the occurrence of such lesions in

increasing numbers with the duration of the disease "from 95 per cent. in advanced cases of 15 years' duration to 21 per cent. among those of 8 years' duration." The experience of Rogers and Muir and of Van Driel (1923) is in rather sharp contrast to that of the workers just quoted. Rogers and Muir from their studies in India are of opinion that "not more than 5 to 10 per cent. of cases of skin leprosy have any disease of the eyes and adnexa caused by leprosy." Van Driel in an examination of 1,300 patients in the Dutch East Indies found complete blindness due to leprosy in only 0.5 per cent. Superficial punctate keratitis, usually mild, was found in 3 to 4.3 per cent., while involvement of the iris was noted on 79 occasions (about 6.1 per cent.).

The eye may be involved in leprosy in one or other of two ways: (a) by lymphatic or blood spread from an active lesion, usually in the vicinity, (b) as a result of abolition of corneal or conjunctival sensation from involvement of the superior maxillary division of the fifth cranial nerve or of paralysis of the orbicularis oculi from involvement of the facial nerve. Different appearances are presented according to the extent of involvement of the various structures of the eye; in cases of eye involvement secondary to blood or lymph spread from a near by focus conjunctivitis, keratitis with pseudo-ptyrius formation and iridocyclitis are the common findings; while in the nerve type of cases we have ectropion, epiphora, corneal ulceration and leucoma and occasionally panophthalmitis. Contrary to the findings of later workers Hansen and Looft described leprosy lesions in the *pars ciliaris retinae* with infiltration of the ciliary nerves. Kirwan (1927) in Calcutta has lately described the slit-lamp appearances in leprosy eyes. According to this worker true iris leprosy is seldom if ever found; the "nodules" of the iris which are sometimes seen are due to exudation. He admits, however, that examination of the iris is difficult owing to corneal implication.

Leprosy lesions in the eye as in other parts of the body may be altered and intensified by the onset of a leprosy "reaction": the exacerbation of eye lesions during the phase of reaction is a complication at once dangerous and difficult to overcome.

(2) *The nose and throat.*—The possibility of the nasal mucosa being the site of the initial lesion in leprosy has already been discussed. The portion of the nose most commonly affected, at least in the early stages, is the mucosa covering the anterior part of the septum and the front of the lowest turbinate bone. Making allowances for the differences in structure of the two areas, the changes that occur in the nasal mucosa are similar in kind to those found in the skin; ulceration with discharge of large numbers of *M. lepræ* is the common sequel of nodule formation in the nasal cavity. Hansen and Looft maintained that the nasal bones are never affected in uncomplicated cases of leprosy. Destruction of the cartilaginous septum in leprosy patients in whom syphilis could be confidently excluded has, however, been reported by Glück, Engel Bey and Rogers and Muir. Wade and Solis (1927), while doubting the rôle of the nose as an important site of the primary lesion in leprosy, call attention to the fact that the infection may persist longer in the nasal mucosa. Examination of the nasal mucosa of 570 patients in whom the skin had become bacteriologically negative under treatment resulted in the recovery of *M. lepræ* on 55 occasions (9.6 per cent.).

Infiltration of the epiglottis, arytenoids and false vocal cords may occur in severe nodular cases of leprosy; ulceration may follow and stenosis of the larynx is not unknown.

(3) *The ear.*—Apart from the very common infiltration of the skin of the pinna and lobule in advanced cases there are no changes in any of the divisions of this organ characteristic of leprosy.

The blood in leprosy.

A not inconsiderable fraction of the literature on the pathology of human leprosy is devoted to the examination of the blood in this disease. We propose to discuss the subject briefly under the following headings:—

(1) Changes in the morphology, numbers and staining reactions of the cellular constituents of the blood.

(2) Serological changes: (a) Variations in the plasma and serum proteins. (b) The presence of specific antibodies to *M. lepræ*. (c) Variations in the physico-chemical constitution of the blood. (d) The Wassermann and Kahn reactions in leprosy.

(3) Changes in the non-protein constituents of the blood.

(4) The presence of *M. lepræ* in the circulating blood.

(1) *Changes in the morphology, numbers, and staining reactions of the cellular constituents of the blood.*

So far as the red blood cells are concerned no alterations of diagnostic or prognostic importance have been described. André and Leger (1908) found poikilocytosis of a mild degree in some of their cases. When we turn to the question of the condition of the white blood cells, however, we find the most contrary views on what would appear to be, at first sight, a very simple problem. Bourret (1908) for example, while admitting that there is nothing characteristic in the white blood cell-picture in leprosy, records eosinophilia as a very frequent finding in his experience—especially in "neural" cases. It does not appear that adequate steps were taken to exclude the possibility of coincident helminthic infections in his cases, and it is further noted that many of the cases were complicated by malaria. Support to Bourret's contention regarding the frequency of eosinophilia is accorded by Gaucher and Bensaude, Darier, and Jeanselme, while Cabral de Leima and Moreira are equally emphatic on the opposite side. The last named worker found mononucleosis in 23 out of 25 "tuberculous" and "mixed" cases. de Marval (1928) reports that the polymorphonuclear neutrophils and the lymphocytes are normal, that the monocytes show a slight increase, that there is an eosinophilia, both relative and absolute—helminths were excluded—and that the blood platelets are normal.

It is probable that examinations of the white blood cells in leprosy have suffered from at least three very considerable defects: (a) Failure to select a series of cases sufficiently large and sufficiently representative of the various types, stages and phases of the disease. Any one can rapidly convince himself that the white blood cell picture in at least one type of case, viz., Muir's "B" type in the phase of acute reaction, is very far from normal. The present author (Henderson, 1927) has shown that the severe reactions caused in this type of case by the administration of potassium iodide induce a polymorphonuclear leucocytosis which may pass the 20,000 per c.mm. mark. (b) Failure to exclude the possibility of coincident diseases which may of themselves, alter the leucocyte picture. (c) Failure to realize the very considerable errors inherent in counting a given number of white cells in the ordinary "push" or "pull" film.

It does not appear unreasonable to insist that if this question is re-investigated, attention be paid to these points. Furthermore it seems to us desirable that in tackling this problem we should avail ourselves of the newer knowledge of the intimate morphology and of the origin of the various types of white blood cells made available by the studies of Maximow, Evans, Sabin and her co-workers and other cytologists, particularly in America.

(2) *Serological changes.*—(a) Variations in the plasma and serum proteins. The majority of workers are in agreement that in advanced nodular cases of leprosy—particularly during the phase of reaction—there occurs an upset of the normal relative and absolute values of the serum proteins, particularly in the direction of an increase in the globulin content, and that in early non-reacting cases no such departure from normal can be detected.

Schöbl and Basaca (1924) find positive globulin-precipitation in leprosy "in all forms" due to an upset balance between salts and globulin "possibly euglobulin." Frazier and Wu (1925) report excess of serum globulin in 17 out of 32 cases of leprosy "of degrees varying from one to three plus"—most marked in nodular cases.

Wade (1925) in his studies in the Philippines finds that the globulin value of the serum increases progressively with the course of the disease, tailing off in recovering cases, and further notes very high values in the phase of reaction and parallelism between formol coagulation and globulin value. It may not be out of place to mention at this point that Napier (1927), the originator of the formol-gel (or leuco-gel) test for kala-azar, denies the occurrence of true positive results in uncomplicated cases of leprosy. Such "positive" results have been reported in leprosy but these are almost certainly due to a failure to apply the standards of "positivity" laid down by the originator of the test.

(b) *The presence of specific antibodies to M. lepræ.*—Refinements in the methods of serological investigation have led to numerous ingenious attempts to devise a "test" which shall be "specific" for leprosy. The literature on this subject is extensive and I do not propose to do more than discuss very briefly the more important features of this subject. A list of references to original sources will be found in the appropriate section of the bibliography.

Complement deviation tests.—Babes (1909) considered that all active cases of leprosy show positive deviation of complement when extracts of highly positive leprosy tissues are used as antigen. His findings have been confirmed by Biehler and Eliasberg (1910), Clegg, McCoy and Hollmann (1913), Cooke (1919) and others. Thomsen and Bjarnhjedinsson (1910), however, in a carefully controlled series of experiments are definitely of opinion that there is no fixation of complement between leprosy tissue extracts and leprosy sera. Spindler (1912) concludes that the complement titre of leprosy sera is frequently within normal limits. Complement deviation in leprosy sera, using extracts of non-leprosy material as antigen, has also been recorded by various workers—Babes and Brusila (1909), Möllers (1913), Nejako and Asakura (1915), Lewis and Aronson (1923), Taylor and Malone (1924), Muir (unpublished observations) and others.

Flocculation and agglutination tests.—In this type of test also numerous (and not infrequently discordant) observations have been recorded. The papers of Slatineanu and Danielopol (1908), Gaucher and Abrami (1909), Babes (1909), and among recent workers those of Muchow and Levy (1924), Rubino (1926), Gomes (1927), Marchoux and Caro (1928) and Gomes and Junior (1928) are of interest in this connection.

The avidity with which a "specific test" for leprosy has been sought is intimately associated with the increasing importance of the rôle played by the laboratory in the diagnosis of disease. The utility of any "laboratory" test or "reaction" is judged by the degree to which it is truly specific and to an almost equal extent by the aid it affords the clinician in the diagnosis or treatment of the disease in question. All the so-called "specific tests" for leprosy fail in one or other or both of these particulars. The complement fixation tests giving positive results not only with *M. lepræ* but also with numerous other acid-fast bacteria—both pathogenic and non-pathogenic—appear to be of the nature of group reactions. The most serious objection, however, to the hitherto described specific tests is that all of them give consistently positive results in the type of case in which clinically the diagnosis is only too obvious, while in the clinically doubtful and bacteriologically negative case they give negative or anomalous results.

(c) *Variations in the physico-chemical constitution of the blood.*—The most important physico-chemical change in the blood in leprosy is the acceleration of the sedimentation time of the red corpuscles which occurs in certain stages and phases of this disease. Observations bearing on this point have been recorded by Puxeddu (1924), Gilbert, Tzanck and Cabanis (1926), Landeiro (1926), Iturbide (1927), Labernadie and André (1927), Molinelli (1928), and Muir (1928) among others. Although there are undoubted individual exceptions, the acceleration in the time of sedimentation of the red blood corpuscles corresponds in a very general way with the extent of involvement of the tissues by the disease

process. Muir in particular has made extensive studies of this phenomenon, and he relies on the sedimentation time not only as an adjuvant to clinical and bacteriological diagnosis but as an efficient guide to treatment.

The present author is of opinion that the sedimentation time in any given uncomplicated case of leprosy is an indication not so much of the extent of leprosy invasion but of the extent to which the cells (particularly the so-called "lepra" cells) of constituent lesions are breaking down. In this view, acceleration of sedimentation time is proportional not so much to cell numbers as to cell instability.* Muir holds the view that some physico-chemical change in the blood plasma precedes acceleration of sedimentation time.

The present author (Henderson, 1929) has recently emphasised the necessity for constant temperatures in making sedimentation estimations, and has correlated certain abnormalities in the sedimentation time with variations in the iso-electric point of the serum.

Henderson, De and Ghosh (1929) investigated the specific gravity of the blood, the surface tension of the serum and the fragility of the red blood cells in leprosy without finding any differences significant beyond the limits of experimental error.

(d) *The Wassermann and other serological reactions in leprosy.*—If one studies the literature relative to the Wassermann reaction in leprosy one notices a gradual change in the attitude of investigators with the passage of time, a change contemporaneous with increased knowledge of leprosy on the one hand and with increased perfection of serological technique on the other.

Babes and Busila (1909) were of opinion that the majority of sera from cases of leprosy give a positive Wassermann reaction with syphilitic antigen, and the findings of these workers were "confirmed" by Meier (1910), Photinos and Michaelides (1912), Sutherland and Mitra (1915), Ariazzi and Pico (1920) and others. As a result, the statement to the effect that "the Wassermann reaction is very frequently positive in leprosy, even in the absence of syphilis" became a commonplace in the literature dealing with the former disease.

The papers of later workers form rather a contrast to those mentioned above. Rogers and Muir (1925) basing their findings on the investigations of Lloyd, Muir and Mitra (1923) conclude that there are probably two factors producing a positive Wassermann reaction in leprosy; one is concomitant syphilis and the other is the breaking down of leprosy granulation tissue, which is more commonly seen in advanced "skin" cases.† In these latter, antisyphilitic treatment often fails to make the Wassermann reaction negative. Pineda and Roxas-Pineda (1926a) report on the examination of 500 leprosy sera by Kolmer's modification of the Wassermann technique. They conclude that the Wassermann reaction is negative in uncomplicated cases of leprosy in the ordinary non-reacting phase, and that when it is positive, complication by syphilis or yaws is indicated. It appears, however, that even these workers are not satisfied that the onset of the phase of leprosy reaction may not induce a positive Wassermann even in the absence of syphilis.

The Kahn precipitation test.—The findings obtained by those who have used the Kahn precipitation test in leprosy are on the whole more in agreement than the Wassermann results.

Yagil and Kolmer (1923) state that the Kahn precipitation test is negative in leprosy sera unless complicated by syphilis, and this finding has been confirmed by Pineda and Roxas-Pineda (1926b). The latter workers also note that the test is negative in uncomplicated cases of leprosy, even during the phase of reaction, and that it is therefore preferable to the Wassermann in detecting treponematosus infection. Arguelles (1926), working in the same area as Pineda and Roxas-Pineda, and with presumably similar clinical material, found the Kahn precipitation test positive in 5 per cent. of leprosy

* Probably, however, both factors play a part.

† Later work has, however, tended to modify this view.

and suspect lepers without history or signs of syphilis or yaws. In "confirmed leper sera" the result was positive in 6.17 per cent. of apparently uncomplicated cases of leprosy. Otero (1927) states that the Kahn test is sometimes positive in uncomplicated cases of leprosy during the phase of reaction, while Greval (1928) denies that this test is more reliable than the Wassermann in excluding syphilis in cases of leprosy.

The Kahn precipitation test is used as a routine in the Leprosy Research Laboratory and Out-patient Department at the School of Tropical Medicine and Hygiene, Calcutta, and also in numerous leprosy treatment centres and out-patient clinics throughout India. Our findings in Calcutta at least, are in substantial agreement with those of Pineda and Roxas-Pineda.

Other Serological Reactions.—None of these has been given a sufficient trial in leprosy and it is difficult to assess their real value.

Ariazzi and Pico, in the paper already quoted, found the Sachs-Georgi flocculation test positive in 19 out of 65 cases (? uncomplicated) of leprosy while Leao (1923) recorded positive findings with the same test in 62.5 per cent. "macular," 39.2 per cent. "tuberculous" and 17.7 per cent. "nervous" cases. Sechi (1925) and Sakurai (1926) found anomalous results on investigating the Wassermann and Sachs-Georgi reactions in leprosy sera, while Pais (1927) recorded 18 per cent. positive Sachs-Georgi in uncomplicated leprosy. Vilanova and Catasus (1927) found very high positive figures with Vernes' reaction in leprosy sera, while Girard and Robic (1928) are of opinion that the Meinicke opacity test is frequently positive in syphilis-free lepers.

Modern opinion is tending gradually towards the view that a positive Wassermann reaction does not occur in uncomplicated cases of leprosy, provided the latest refinements in technique are used. The Kahn precipitation test would appear to be as reliable as the Wassermann reaction, and in view of its greater simplicity it is preferable to the latter in small hospitals and treatment centres.

(3) **Changes in the non-protein constituents of the blood.**—The progress that has been made in recent years in methods of chemical examination of the blood has led to investigations along this line in connection with leprosy.

The cholesterol content of the blood has been investigated by Boulay and L  ger (1923), Balbi (1925), Gomes, Leitao and Wancolle (1927), and Boyd and Roy (1928); non-protein nitrogen, uric acid, sugar and chlorides by Paras (1926), and by Otero and Hernandez (1928); calcium by Underhill, Honeij and Bogert (1920), Concepcion and Salcedo (1926), Lemann, Liles and Johansen (1927), Villela (1928), Cruz, Lara and Paras (1928), and the alkali reserve of the plasma by Paras (1927). There appears to be no change in the blood or serum content of any of these constituents which can be regarded as in any sense typical of leprosy.

(4) **The presence of *M. leprae* in the circulating blood.**—*M. leprae* have been noted in the circulating blood of lepers, usually advanced skin cases, particularly during the phase of reaction. The organisms may be free in the blood plasma or may be detected inside leucocytes, usually (it is said) mononuclears. Hollmann (quoted by Muir) in an analysis of the literature notes that of 44 investigators only 13 failed to find *M. leprae* in the circulating blood, and that Crow found this organism in the blood of no fewer than 21 out of 24 cases examined.

Honeij (1915) had 9 successes in 28 examinations. Iyengar (1919) reports 4 positive findings out of 10 "nodular" cases examined, 1 positive in 20 "anaesthetic" cases, and 2 positives in 10 "mixed" cases.

Leprous lesions of the respiratory system.

(1) **Larynx and trachea.**—The common sites of leprosy infiltration of the larynx are the epiglottis, the false vocal cords and the arytenoid cartilages. Huskiness of the voice is a common clinical manifestation and the subsequent organization of the leprosy granulation tissue may lead to laryngeal stenosis of a degree sufficiently

severe to call for tracheotomy. Many of the most severe cases are complicated by coincident syphilis. In the trachea no characteristic changes have been described.

(2) **Lungs.**—Hansen and Looft doubted the existence of true leprosy of the lungs. Later workers have, however, described and figured what appear to be undoubted lesions of the lung caused by *M. leprae*. Lesions of all degrees of severity have been recorded. As Babes and Moscu, Uhlenhuth and Westphal and others have shown, the lungs may appear to be normal on naked eye examination and yet *M. leprae* may be demonstrable on microscopic examination. At the other end of the scale there may occur peribronchitis, caseous softening and even gangrenous bronchial cavities.

While there does not appear to be any reasonable doubt regarding the occurrence of true leprosy lesions of the lungs, a much commoner finding in the experience of the majority of investigators is the onset of pulmonary tuberculosis as a complication in advanced cases of leprosy.

Leprous lesions of the gastro-intestinal tract.—Sugai (1921) describes the occurrence of superficial nodules on the tongue and tonsil with *M. leprae* in the salivary glands in some of his cases. Typical leprosy lesions of other portions of the gastro-intestinal tract have not been described. Fajardo (1924), however, claims to have found *M. leprae* in the faeces in 100 per cent. of severe nodular cases, in 80 per cent. of cases with fewer nodules and in 25 per cent. of nervous cases.

Leprous lesions of liver, pancreas and spleen.—The presence of leprosy lesions in the liver has been recognized since the days of the earliest workers. Hansen and Looft described the occurrence of round cell and bacillary infiltration along the portal vessels and in Glisson's capsule. Incidentally Hansen's figures clearly show *M. leprae* in what we now know as K  pffer's stellate cells, which he himself called the "endothelial cells of blood vessels." Organisms were also present in the white blood corpuscles within the hepatic blood vessels, but there were none in the liver cells themselves. Jadassohn however in Kolle and Wassermann's *Handbuch* quotes Doutrelepon and Wolters, Uhlenhuth and Westphal and others to the effect that *M. leprae* are occasionally found inside liver cells. Sabrazes (1925) reports massive involvement of the liver (and spleen) in an advanced case without *M. leprae* in the bile. Accumulations of "reticulo-endothelial cells" loaded with organisms were found in both organs. Rogers and Muir conclude that "leprosy bacilli are rare in (spleen and) liver" while Wade and Rodriguez note that the liver may contain *M. leprae* without being grossly disturbed either in function or in structure. In advanced nodular cases there is frequently evidence of amyloid degeneration in the liver; involvement of the lymphatic glands in the hilum of the organ is common.

Babes, Sch  ffler, Uhlenhuth and Westphal have found occasional *M. leprae* in the stroma of the pancreas, but lesions of this organ are extremely rare.

Pure leprosy lesions of the spleen occur not infrequently. Cellular proliferation occurs around the vessels and along the trabeculae; there is an apparent increase in numbers of the stellate cells of the reticulum and "globi" are sometimes seen. The lymphatic glands in the hilum of the spleen, like those in an analogous situation in the liver, are frequently involved and amyloid degeneration is found in advanced cases.

Lesions of the circulatory system.—No changes characteristic of leprosy have been described in the heart or large blood vessels.

Lesions of the urinary system.—In the experience of the majority of workers the kidneys seldom show definite leprosy lesions: De Buermann and Gougerot (1914) however describe acute and chronic leprosy nephritis and also bacill  mia of leprosy origin without signs of renal lesions. Rake (1888) found *M. leprae* in the kidneys in 49 examinations; Lagane (1912) and Honeij (1915) also report the occurrence of *M. leprae* in the urine. As in other organs amyloid degeneration is common in the terminal stages of advanced cases. No characteristic changes have been found in the urinary bladder.

Lesions of the reproductive system.—Infiltration and destruction of the testes is very common in advanced nodular cases and such patients are not infrequently sterile. Hansen and Looft described *M. lepræ* both in and between the seminiferous tubules and also in the endothelium of the small vessels of the testes. In their experience the seminal vesicles are seldom involved.

Sugai (1911) notes the presence of organisms in the seminiferous tubules and in the duct of the epididymis, but very rarely in the ejaculatory ducts or in the seminal vesicles. Amyloid degeneration of the small vessels of the testes is commonly found. Wade and Rodriguez and Kobayashi (1924) have described the occurrence of *M. lepræ* in the seminal fluid. The latter worker proposes examination of the testicular puncture fluid as a method of diagnosis in early cases. During the phase of reaction in advanced cases a very painful acute orchitis may occur.

The ovaries may be involved in leprosy—but not so frequently as the testes. Cellular infiltrations containing *M. lepræ* and not infrequently visible to the naked eye have been described by Arning, Babes, and Glück among others.

The mammary glands may be invaded by tuberculous leprosy; and Babes has occasionally seen *M. lepræ* in the gland cells. Powell (1924) has recorded hypertrophy of one or both nipples in 290 out of 385 male lepers examined and also in 3 of 7 female children below the age of puberty.

Pineda (1928) found *M. lepræ* in 53 per cent. of 107 placentas examined at Cullion and in 24 per cent. of umbilical cords from the same group of cases.

Lesions of the endocrine glands.—Babes and also Lie have described the occurrence of *M. lepræ* in the suprarenals. Beyond this nothing is known regarding the changes occurring in the ductless glands incidental to leprosy.

The "leprous reaction."—The leprous reaction or "lepra fever" is a phenomenon familiar to all leprologists and its clinical manifestations and treatment have been described by many workers. During this phase of leprosy there occur signs and symptoms referable both to a general systemic disturbance and to the exacerbation of local lesions. Chief among the former are fever, of a continued or irregularly remittent type, acceleration in the sedimentation time of the erythrocytes, increase in the globulin content of the serum, and in marked cases a very definite polymorphonuclear leucocytosis. The local manifestations, depending as they do on exacerbation of pre-existing lesions, are very protean. Hence we have one case characterized mainly by intense erythema and, it may be, breaking down of skin lesions; a second by intense neuritis with possibly abscess formation in the trunk of a nerve; a third by grave iridocyclitis and so on. While an exact correlation cannot, naturally, be established, there is in a general way a rough correspondence between liability to reaction and the degree of infection in a given case. Muir in particular is emphatic that any factor tending to lower temporarily the general resistance predisposes to the occurrence of the phase of reaction; chief among these factors are: (i) the commonly used "anti-leprotic" drugs, particularly potassium iodide; (ii) the incidence of acute or chronic infectious diseases; (iii) irregularities in diet or semi-starvation.

The intimate nature of the leprous reaction is not yet known. Briefly there are two theories; (a) that it is due to the simultaneous break-down of large foci of leprous granulation tissue with consequent release of a large amount of leprotic "toxin," (b) that it is a protein hypersensitization phenomenon. These views are largely complementary. Lowe (1929) has recently suggested a third possibility, viz., that the reaction is a toxæmia, the toxin being the result of the union of an antigen (*lepra bacillus*) with the immune body or amboceptor produced by the defensive mechanism of the tissues. Study of the mode of action of the so-called "reaction-producing drugs" and especially potassium iodide has tended to incline the present author to the view that the onset of

the phase of leprous reaction can be explained in part at least on purely physico-chemical grounds. It seems to him that potassium iodide owes its remarkable reaction-producing power to the fact that it is a highly ionisable salt. Partial support is lent to this view by the fact that combinations of iodine with highly complex molecules, for example protein molecules, are almost entirely devoid of reaction-producing activities.

In a severe case of the nodular type, vast numbers of the so-called "lepra" cells are a prominent feature of the lesions. Many of these cells are crammed full of *M. lepræ* and their protoplasm has undergone fatty degeneration; at the surface of the cell membrane there must be (theoretically at least) considerable instability of equilibrium. The sudden appearance in the tissue fluids of a highly dissociated substance may therefore lead to a still further diminution of cell surface stability, to the occurrence of widespread cytolysis and the onset of the reactionary phase.

The scope of the present paper does not permit a description of the varied histological pictures presented by leprous lesions during the phase of reaction—these it is hoped to incorporate in a future paper, nor of a discussion of the effects (harmful or otherwise) of a reaction on the course of the disease as a whole. A list of the more important papers will be found in the appropriate section of the bibliography.

SUMMARY.

An attempt has been made to collate under one heading certain observations on the bacteriology and pathology of leprosy which would seem to be important for the further study of the disease. That there exist large gaps in our knowledge even of the very fundamentals of the subject cannot be gainsaid. For this there are several reasons: (i) the markedly chronic and non-fatal nature of the disease; (ii) the very natural reluctance on the part of research workers as a whole to bend their energies towards the elucidation of the problems of a disease which has been regarded in all times with horror and loathing; (iii) the two prime failings of medical research (a) the isolated observation, (b) failure to correlate pathological with clinical findings. Both have been responsible for the most diverse statements regarding the findings "in leprosy" which ensue as the result of particular examinations.

It is hoped that this epitome with its accompanying bibliography may prove of assistance to other workers in the field of leprosy research in suggesting further lines of approach to the manifold problems of this disease.

ACKNOWLEDGEMENT.

I am indebted to Dr. E. Muir, M.D., F.R.C.S. (Edin.), Officer in charge, Leprosy Research Laboratory, the School of Tropical Medicine and Hygiene, Calcutta, for permission to submit this paper for publication.

BIBLIOGRAPHY.

Following is a list of the more important and accessible papers dealing with the bacteriology and pathology of human leprosy: these aspects of the subject are also described in greater or less detail in the following textbooks:—(1) *Hansen and Looft—Leprosy in its Clinical and Pathological Aspects*, translated by Norman Walker, M.D., F.R.C.P. Bristol, John Wright & Co. (2) *Rogers and Muir—Leprosy*. Bristol, John Wright & Sons. (3) *Wade and Rodriguez—A description of leprosy*. Manila, Philippine Health Service. (4) *Kolle and Wassermann—Handbuch der pathogenen Mikroorganismen*, Jena, Gustav Fischer. Jadassohn's article on leprosy in the latest (1928) edition of the *Handbuch* is excellent.

especially the new academic Diploma instituted this year by the University of London. This course is planned in a broad, practical spirit, and gives promise of a great advance on anything which has hitherto been systematically attempted with regard to public health teaching. Two large centres of public health administration have been secured as demonstration areas, an advisory committee of experts of the first standing in the Public Health Service appointed, and a scheme of special lectures arranged to be given by men and women eminent in their subjects; the course also provides for visits to works, factories, slum areas, garden cities, schools, and other institutions.

The courses of study in tropical medicine and hygiene are maintained at a high level, and include a special short course in hygiene for business or professional men and women proceeding to the tropics.

The University Grants Committee have intimated that the Treasury has sanctioned a recurrent grant-in-aid at the rate of £40,000 a year, but impress upon the School the necessity for taking all possible steps to secure an increased private income from the Colonies, from public or private subscriptions, and in other ways.

The Prince of Wales in his speech at the Opening Ceremony said that, if the work of this School were properly conceived and carried out, there should follow a steady decrease in preventable diseases, suffering, and death, and that by its work in this connection the School would be judged. The Board state that they have every reason to believe that Dr. Andrew Balfour and his colleagues in this post-graduate School will be well content that their work shall be judged by the standard which His Royal Highness has laid down, and will maintain that high tradition in teaching and research which their contemporaries would expect.

AN HONOUR FOR BENGAL.

AN Honorary Life Fellowship of the Ross Institute has been bestowed on Dr. Rai G. C. Chatterjee Bahadur of Bengal. During the past fifty years malaria has been spreading in many districts of Bengal. It has caused great misery, sickness, and loss of life. Within living memory hundreds of villages have been decimated by the disease; thousands of acres of once prosperous and highly cultivated land have been abandoned, or are cultivated by temporary labourers who do not dare make a home on the land; populous towns have been reduced to the status of miserable fever stricken villages; and the jungle is creeping in to blot out all traces of man.

All interested in the welfare of Bengal and its people have viewed the outbreak with grave concern. Government, assisted by both Europeans and Indians, have considered how best the disease could be stayed, and have adopted such means as appeared most helpful. But to Dr. Rai G. C. Chatterjee Bahadur in 1908 came the idea of rallying his disheartened and stricken fellow countrymen to apply the teachings of Sir Ronald Ross to their own salvation, through an Anti-Malarial League. In 1913 work was commenced in one village with volunteer labour. Its success attracted other villages to the movement. With the help of the distinguished Bengalee gentlemen, Dr. Bentley, and others, a Central Co-operative Anti-Malarial Society was formed in 1919 to assist in the formation of Local Co-operative Societies. To-day a network of some 2,000 villages throughout Bengal are making a great and successful effort to control malarial and other diseases.

This achievement, the first of its kind in Asia, has been largely due to the great but unassuming personality and splendid self-sacrifice of Gopal C. Chatterjee, and the Ross Institute desires to recognize his work by bestowing on him an Honorary Life Fellowship.

SIXTH INTERNATIONAL MEDICAL CONGRESS OF LABOUR ACCIDENTS AND PROFESSIONAL ILLNESSES.

August 1931, Geneva.

AFTER agreement between "The permanent International Commission for study of Labour Medicine" and "The permanent International Commission for

Medical News.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

(UNIVERSITY OF LONDON.)

At the Annual Meeting of the Court of Governors of the London School of Hygiene and Tropical Medicine held on November 27th, 1929, in the Lecture Theatre of the new School Building in Gower Street, the Board of Management of the School, whose Chairman is Lord Melchett, presented their Fifth Annual Report. Sir Holburt Waring was in the Chair. The lecture theatre is probably the finest of its kind in London.

In the year under review, ended 31st July, 1929, the new home of the School, its equipment, and the development of its organization advanced steadily towards completion. On 18th July the Prince of Wales formally opened the new building, which His Royal Highness described as a notable addition to the homes of learning in London.

Special reference is made in the report to the new course of study designed to prepare candidates for the examination for the Diplomas in Public Health, and

Professional Illnesses" it has been decided that the Sixth International Medical Congress of Labour Accidents and Professional Illnesses will be held in Geneva in August 1931.

The following questions will be studied:—

(1) *Slow results and evolution of the traumatic wounds of the spine.*

(2) *Traumatism of blood-vessels (arteritis and thrombophlebitis).*

(3) *Cutaneous infections in relation with Labour Accidents.*

(4) *Previous state by consequences of Labour Accidents.*

Further there will be a certain number of free questions, the subject of which shall be left to their authors' option.

Participation:—Every doctor whom these questions interest can partake at this congress.

Information:—For information apply to the General Secretary, Dr. Yersin, rue du Rhône, 1, Genève.

ANNOUNCEMENT OF THE SEVENTH POST-GRADUATE COURSE IN OPHTHALMOLOGY. VIENNA, 1930.

The seventh special course for post-graduate study in ophthalmology will be given between 1st October and 5th December, 1930, under the auspices of the American Medical Association of Vienna at the I and II Eye Clinic of the Allgemeines Krankenhaus, Vienna, Austria.

This intensive post-graduate instruction was first originated in Vienna in 1922 as a result of a suggestion by Dr. Edward Jackson of Denver to Prof. F. Fuchs. Prof. E. Fuchs is kind enough to participate in the programme. Prof. I. Meller and Prof. K. Lindner, chiefs of the Eye Clinics, have again consented to take an active part. The other lectures will be given by Prof. Lauber and A. Fuchs, the Docents Bachstetz, Guist and Pillat, and Assistants Dr. Safar, Dr. Urbanek, Dr. Fischer and Dr. Subal. Professors, Docents and Assistants of other departments will deliver lectures in their respective subjects: Prof. Kolmer on comparative ophthalmology; Prof. Schüller on Röntgen-rays; Prof. Hirsch on the Hypophysis and Sinuses; Docent Kofler on the modified West-operation; Docent Fuhs on Radium-treatment; Assistant Pollitzer on Embryology.

The course has been so arranged that the field can be covered systematically and comprehensively in the allotted time. A preliminary knowledge of ophthalmology is pre-supposed.

Concerning operations, only lectures with demonstrations will be given. In refraction, only advanced work will be given. In ophthalmoscopy, the non-electric ophthalmoscope will be used.

The entire course is given in English for a minimum of ten, and a maximum of sixteen men. The fee is \$750 per man. Applications with a certified check for \$50 should be sent to Prof. A. Fuchs, Vienna, VIII, Skodagasse 13. Applications are accepted in order of priority.

Further information can be secured by writing to Prof. Dr. A. Fuchs, Vienna, VIII, Skodagasse 13 or to the American Medical Association, Vienna, VIII, Alserstrasse 9, Café Edison.

Current Topics.

A Useful Hint for Intravenous Injections.

(Abstracted from *The Medical Press*, September 25th, 1929, p. 248.)

The present age of medical practice has adopted wholeheartedly the practice of intravenous injections of blood, saline, glucose, or other material. These injections have often to be repeated, and it not infrequently happens that considerable difficulty is experienced in finding a suitable vein after the first or second injection has

been given. For obvious reasons it is preferable to use the same vein repeatedly; it is less disturbing to the patient at the time, and in cases where the vein has first to be exposed it involves less discomfort afterwards. But there are practical objections to this course after an exposure of the vein has been made, for the finish of the procedure is usually a skin suture intended permanently to close the incision if not to obliterate the vein. Dr. C. L. Larkin, of Waterbury, in Connecticut, published in the August number of *Surgery, Gynecology and Obstetrics* a short note describing the procedure which he has adopted when performing an intravenous injection in bulk, and intending subsequently to repeat the injection through the same vein. It seems to us worth quoting for the benefit of our readers. Having exposed the vein he ties it off with a plain catgut suture at the lower end of the wound, then grips the vein just above the suture with a fine pointed forceps, and cuts with a scissors a small V-shaped flap above the suture, the apex of the flap pointing towards the suture. The fine forceps remain in position on this flap, and retracts it upwards while the injection is running in. When the injection has been completed the flap is allowed to fall back into position, the forceps removed, and the skin edges approximated by means of a black silk suture tied in a bow knot. This suture passes through the skin and superficial fascia opposite the base of the flap, and then under the vein, to come out directly opposite on the other side of the wound. Dr. Larkin finds that by this method the same vein may be used again and again, simply by untying the knot and picking up the flap.

Fatal Laryngeal Obstruction by a Fish.

(Abstracted from *International Medical Digest*, Vol. XV, July, 1929, No. 1, p. 63.)

In a letter to the *British Medical Journal*, Dr. N. A. Dyce Sharp writes from Nigeria reporting a fatal case of laryngeal obstruction by a fish. He states that: "A few days ago a native woman was catching fish in the river with a basket net, and while transferring the small fry from the net she put one between her lips, her hands being full. The fish apparently gave a jump, and a moment later the woman was seen to fall, struggling to get her breath. Her friends at once opened her mouth and endeavoured to remove the obstruction; they failed, and after five minutes all her convulsive movements ceased. The body was at once brought to the mortuary, with a request for a necropsy; only afterwards did I discover that this was designed to determine whether she was a witch herself or whether she was bewitched, and here I failed! On removing the larynx and as much of the pharynx as possible, I found a small fish, 3½ inches long, wedged firmly down the trachea with the snout lying transversely between the vocal cords. Minute spines on the dorsal surface and at the border of the gills effectually prevented its extraction upwards, and indeed, the tail had already been pulled off by the victim's friends. As the width of its head was about 23 mm. and the breadth about 17 mm., the larynx was most completely and exactly occluded. This is well shown in the preserved specimen, which was fixed in an alcoholic solution of perchloride of mercury. A smaller or a larger fish could not have caused so complete an obstruction."

Rationale of Digitalis Therapy in Pneumonia.

By R. C. TREIMAN.

(Abstracted from *International Medical Digest*, Vol. XV, No. 2, August 1929, p. 75.)

BECAUSE of its pre-eminence as a drug in heart failure, it is only natural that digitalis should have come into use for supporting the circulation in pneumonia. There is at present, however, an almost universal lack of agreement as to its usefulness.

In the less severe cases of lobar pneumonia the changes in the heart and circulation are no greater than in any

febrile process. In the more severe and fatal cases clinical examination may reveal alarming changes in the general picture—the pulse, blood pressure and heart. Breathing, difficult throughout the disease, may become shallow, rapid and inefficient. Cyanosis in some degree is almost constantly present. It has already been mentioned that complete irregularity with auricular fibrillation or flutter occurs in a significant number of cases. Some form of heart-block is not infrequent. In overwhelming infection the blood pressure often begins to fall early, the diastolic more proportionately than the systolic. On the other hand, desperately ill patients may have a fairly high systolic and diastolic pressure up to the period immediately preceding exitus. Dilatation is indicated by an increase in cardiac dulness; the heart sounds become less distinct and the apex beat more diffuse. The long diastolic pause is greatly shortened and the sounds, approaching each other in quality and timing, assume a foetal character. When death is near, the heart sounds become still fainter, the pulse more rapid and weaker, and all the signs of a vasomotor collapse may be present; ashy cyanosis, cold hands and feet, clammy perspiration and a sudden drop in blood pressure. The end may come with tragic suddenness, often within three or four days of the initial rigor.

When there is much clinical evidence of circulatory failure in severe or terminal pneumonia, it is necessary to remember that tachycardia, dyspnoea, cyanosis and, indeed, dilatation of the heart may occur without cardiac or circulatory incompetence. Before deciding to give any cardiac drug, one should analyze the various factors underlying each symptom and inquire what, if anything, one could hope to accomplish by changing the state of the circulation.

Tachycardia is a normal reaction of the heart to fever and toxæmia. In pneumonia there is an added factor of increased functional demand on the heart owing to anoxæmia. The decrease in lung area available for aëration of the blood with, perhaps, an atonic state of the peripheral vessels resulting from toxic action on the vasomotor centre, conspires to call forth tachycardia as one method of increasing circulatory rate. To slow the heart under such circumstances might be to remove from the forces of defence of the body a compensatory mechanism designed to meet the demands of the tissues.

It might still appear desirable to increase the period of rest of the cardiac muscle, since any increase in rate is at the expense of the diastolic or rest-period, normally about 13 out of 24 hours. However, the rate in pneumonia is usually not so high, nor is tachycardia present for so long a period that this *per se* should be an important consideration. Another reason for slowing the heart might be to maintain cardiac output, as it is generally believed that tachycardia tends to reduce the period of diastolic filling as well as the systolic output of the individual beats.

In the ordinary case of pneumonia, it would therefore appear unnecessary and perhaps meddling to attempt therapy directed at the tachycardia itself. When auricular fibrillation or flutter develops during the course of pneumonia, the administration of digitalis should be attended by the same brilliant results that are obtained in fibrillation occurring under any other circumstances.

It is necessary to distinguish the dyspnoea and cyanosis in pneumonia from that in cardiac disease. The fundamental fault responsible for cardiac dyspnoea is obviously to be found, not in the nature of the blood, but in the rate at which it is pumped; in the heart itself; and the same may be said for the cause of the cyanosis in cardiac disease. In pneumonia, on the other hand, there is not only a change in the blood, but there are also several factors quite independent of circulatory failure combining to produce dyspnoea and cyanosis.

Animal experiments have shown that the heart muscle in pneumonia is essentially normal and that an impaired myocardium is an infrequent cause of death in this disease. However, Brooks and Carroll, and Stone found degenerative changes, but these were no doubt due largely to a toxic action, and it may be assumed that the changes

are present to a lesser degree in the usual (less toxic) cases.

In lieu of direct methods of measuring myocardial function, changes in the heart size may furnish some evidence of the functional condition of the heart muscle.

The factors involved in the production of dilatation must be carefully considered. Probably those hearts whose muscles are already weakened or damaged by a severe toxæmia are more susceptible to other influences tending to produce dilatation. Starling and his pupils have shown that when the work presented to the heart is suddenly increased, the outflow of blood fails for a time to equal the inflow. The heart therefore gradually dilates until a new balance with equal intake and output of blood, but with an increased heart volume, is attained.

From this it appears that dilatation must be an adaptive phenomenon, increasing a temporarily decreased volume output. Such a dilatation might be termed "physiological" and is probably the type that usually occurs in pneumonia. However, when dilatation is not accompanied by increased systolic discharge, there is the so-called "pathological dilatation" which occurs when the myocardium is so damaged or atonic that increased length of the muscle fibre exceeds a critical value and can no longer be compensatory. This latter type probably occurs in a heart severely damaged by toxæmia, or with very extensive pulmonary consolidation.

That respiratory paralysis is the essential factor in fatal pneumonia is the belief of Newburgh, Means and Porter. That death in pneumonia can at least in part be attributed to vasomotor collapse is the contention of many others. The falling diastolic pressure, the moist skin, the gray-ashy cyanosis and the rapid pulse, so often seen in severe and fatal cases, lend support to this view.

The former belief that digitalis has no effect on the febrile heart has been thoroughly disproved.

Its possible toxic action also must not be overlooked. Digitalis is practically useless unless the dosage is sufficient materially to impair conduction. This impaired conduction is itself capable of causing toxic effects. While there is a fairly wide margin between the therapeutic and the fatal dose, the therapeutic representing about a third of the fatal, the experiments of Hirschfelder suggest that in febrile conditions therapeutic effects are obtained with relatively small amounts and that doses ordinarily considered therapeutic may cause toxic symptoms.

Irregularities of the heart produced by digitalis occur not infrequently. The most common early effect is vagus stimulation (sinus irregularity). The rate may fall to fifty or even less, so that syncope may occur between the contractions.

Digitalis may have a tendency to produce partial heart-block; it may occur with relatively small doses and may be permanent. It is possible, also, that digitalis may bring on auricular fibrillation where it is used in anticipation of fibrillation.

No slowing of the heart should be expected in pneumonia except where fibrillation intervenes.

While a rise of blood pressure through digitalis is often seen in animals, no rise occurs in man in either health or disease; indeed, even a decrease in diastolic pressure in cases with normal rhythm has been observed. The blood pressure in the usual case of pneumonia does not materially change. In the severe and fatal cases, however, where the blood pressure often does fall markedly, it is very doubtful whether digitalis can be of any value since the drop is probably due either to myocardial damage by toxæmia or to vasomotor paralysis.

Conservative observers are of the belief that the only indications for digitalis are two, viz., tachycardia due to auricular fibrillation, and decompensation. There are some investigators who assume that the effects on the myocardium produced by digitalis in the decompensated heart can be utilized in strengthening the heart in pneumonia. Such effects are supposed to involve the cardiac properties "tone" and "contractility."

It is to be deprecated, however, that all too often results obtained in experiments dealing with one or more of these so-called "heart properties" are unqualifiedly assumed, *a priori*, to show that the heart could be strengthened, sustained, stimulated, its volume output increased, etc., if the heart's "properties" could be augmented by digitalis. For it must be remembered that no one has ever shown what mechanism is responsible for the beneficial action of digitalis except in auricular fibrillation. Those who give digitalis in pneumonia to increase minute volume output not only must bear this in mind, but also they must not lose sight of the fact that it is even questionable whether digitalis actually can increase cardiac output.

The use of digitalis to increase cardiac output in the pneumonic heart is on a very uncertain basis.

Dilatation within physiological limits is an adaptive phenomenon in the usual case of pneumonia, making the heart a more efficient pump. In the severe cases, where the damaged heart tends to enlarge beyond these limits, digitalis, while enabling the fibres to draw on their reserve force by raising the strength of their contraction, does not raise the limit strength, and, as Hirschfelder points out, when that limit is already approached, digitalis may spur the fibres too far and drive them to overstrain and death.

Those who give digitalis as a routine measure must also realize that they are adding a potential poison of uncertain strength to a system already intoxicated. Finally, the routine use of digitalis is to be deprecated on the general principle that a drug is not to be prescribed until some special indication for it appears.

Notes on the Treatment of Diabetes in General Practice.

By D. C. HARE, C.B.E., M.D., M.R.C.P.

(*The Practitioner*, September, 1929, Vol. CXXIII, No. 3, p. 202.)

THE discovery of improved methods of diagnosis and treatment has brought diabetes into the category of chronic diseases which should be faced optimistically by doctor and patient, for though the diabetic regime is a hard one, yet, speaking generally, it is not incompatible with a life of mental and physical vigour. The first condition of success is to obtain the patient's confidence and intelligent co-operation, for he will have to regulate his habits according to rule for the rest of his days. The treatment of diabetes may relieve symptoms completely without improving the pancreatic function or permitting of any relaxation of the regime; the natural instinct is to believe that "feeling well" is the same thing as "being well," which for the average person means abandoning all precautions. This in the diabetic leads rapidly to complete relapse.

METABOLIC BALANCE IN THE DIABETIC.

The diabetic never has a perfectly balanced metabolism, no matter how carefully the treatment may be regulated. In practice a condition of balance is approached when the urine remains free from sugar on a fixed diet (with insulin if necessary), which is sufficient to satisfy the normal appetite and to maintain a normal body-weight. The study of such a case by chemical tests of the blood shows, however, that the blood-sugar is more variable than in the normal, and is frequently above the normal concentration. The more severe the case the wider are the variations.

It has been taught that the ideal condition in the diabetic is that in which the sugar concentration never exceeds the normal maximum; this can be achieved by keeping the glycogen stores empty, and in a severe case only in this way, a condition in which the depleted patient suffers from languor and depression. Physical and mental vigour, which are the accompaniment of well-fed tissues, cannot be experienced when the patient is required to live for his energy supplies from hand to mouth, or from one meal to the next, with no reserves to draw from in the interval. Reserves are accumulated slowly as soon as the patient is given a diet with slight excess

over the daily requirements; at first, while the reserve is still below normal, blood-sugar remains low and glycosuria is absent for the whole twenty-four hours, and the patient appears to be in a condition of metabolic balance, but as the reserves accumulate and a more normal state of nutrition is approached, glycogen becomes available for mobilization when tissue energy is required, and this leads again to high blood-sugars and intermittent glycosuria. A break in the diet is suspected or a deterioration in the pancreatic condition, though neither is, in fact, the cause, and the patient is at this stage feeling much better than in his earlier under-nourished condition. The desire of the patient is not merely to be kept alive, but to carry on an active life, and the aim of treatment must be to secure a contented energetic patient rather than one whose blood-sugar may be found normal at all times and whose urine is above reproach.

DIET TREATMENT.

The treatment of acute diabetes in pre-insulin days was inevitably that of permanent under-nutrition preceded by fasting, often prolonged for two to three days, till the urine was sugar-free, when a "ladder diet" followed under the scheme introduced by Allen. This treatment should no longer be employed for the severe case already under normal weight, as it only prolongs the period of invalidity. A normal nutrition or "maintenance diet" should be given from the first, i.e., a diet calculated to maintain the normal body-weight in health; when at rest a low diet only is required, say ten calories to the pound of body-weight, and as activity increases the allowance must be raised gradually. The proportions of the three food constituents, carbohydrate, protein and fat are calculated and given in sufficient amount to produce the total calorific value required; the values may be obtained from published tables—those by Harrison and Lawrence are convenient for general use. After a few days, if glycosuria is still present, insulin is given.

The detailed regulation of diet will not be described here, there are many good books on the subject. The need for variety should not be forgotten, it is inhumane to condemn the patient to eat the same food daily. It should be remembered that the nutritional values vary widely, first in the food as bought, secondly, as cooked, and thirdly, as absorbed in the stomach and intestines. After the initial stages of treatment the patient should be given a list of foods forbidden and foods allowed and be taught to choose a varied diet of approximately correct values; this can be checked occasionally by obtaining a record of the actual menus for a week with the weight of food taken.

THE WEEKLY WEIGHT RECORD.

This is an important means of studying progress and the results of treatment, patients who are above or below the desired weight should lose or gain accordingly, and diet and insulin are adjusted to this end.

TESTING THE URINE.

Tests for sugar and acetone should be made daily when treatment is being begun, when any change of treatment is being introduced and when infection or other illness occurs. When treatment is established the sugar test should be made weekly on a mixed sample of urine, if possible on a complete twenty-four hours collection. All intelligent patients should be taught to do the sugar test and to use the results to regulate their diet and insulin dose within prescribed limits; they can thus detect if anything is going wrong and lapse from diet rules will bring a reminder and a check.

INSULIN TREATMENT.

The supply of insulin given hypodermically twice or thrice daily cannot replace the normal mechanism of secretion by the regulation of the blood supply to the gland. Insulin by injection is supplied to deal with absorption of alimentary carbohydrate taken in at a known time, but when the tissue sugar rises as the result of the mobilization of the glycogen reserves, insufficient insulin may be available to metabolize it and an excessive

rise and temporary glycosuria cannot be avoided. At another time, heavy exercise following a large dose of insulin may produce a temporary hypoglycæmia which does not occur with moderate activity. Experience has shown, however, that in practice the adjustment of the dosage is not difficult in adult cases. The easiest way of initiating the treatment is to begin with a moderate dose and increase it rapidly or slowly according to the needs of the case while keeping the diet constant; when the patient's "balance" is being worked out, changes in both diet and insulin dose should not be made simultaneously. In the averagely severe case insulin may be begun with a dose of 10 units twice daily, increasing every forty-eight hours by 10 units daily till a dose of 50 units daily is given. This is an average maximum dose, and although the diet may not be quite balanced it will be well to pause before making a further advance; a reduction in the carbohydrate allowance may be necessary to secure the required result. Doses of 25 units at a time should seldom be exceeded, and a large evening dose should be avoided.

The reaction to insulin can be watched with some accuracy by means of urine tests while glycosuria is still present. The effect in lowering the blood-sugar and the sugar output begins about a quarter to half an hour after the dose and reaches a maximum from two to four hours after. If the dose is not enough to lower the blood-sugar below the "renal threshold for sugar," i.e., the concentration at which sugar passes out of the blood into the urine, the urine secreted will contain sugar and the dose can safely and with advantage be increased. To carry out the test, separate urine specimens are collected; the bladder should be emptied about a quarter of an hour after the injection (this specimen will probably contain sugar) and at two-hourly intervals. The specimens at two and four hours after the injection and meal are those which will probably be sugar-free, the time of return of urine sugar can be noted and another insulin dose introduced or the amount of the dose increased. When glycosuria is only occasional or apparently absent, a total twenty-four hour collection should be made and tested, and if sugar is found, the time at which the "leak" occurs can be traced by the examination of separate specimens; but, as explained above, it is usually impossible to keep the blood-sugar of the well-nourished severe diabetic continuously normal with two or even three doses of insulin daily, and urine-sugar leaks occasionally occur and do not call necessarily for change in treatment.

Hypoglycæmia of slight degree occurs frequently in the course of treatment and need cause no anxiety. For evidence of slight attacks the patient's own account of his symptoms must be relied upon; and those who have been warned are sometimes over-anxious and relate suggestive symptoms due to other causes. Giddiness, "an all-gone feeling," "eyes coming over dark," sweating and trembling, when noted from two to four hours after insulin may be attributed to low blood-sugar concentration. It is particularly likely to develop after unusually heavy muscular exertion. The treatment is to lessen the insulin or increase the food or add a small amount of food at the time when symptoms are likely to develop. Patients on large doses should be taught to cut down the dose before undertaking heavy work. Severe hypoglycæmia need not be feared in an adult on an ordinary dose that has been gradually reached; it has occurred after the massive doses that are given in the treatment of diabetic coma. Fits and severe symptoms are produced sometimes in young children of three or four years on moderate doses, and may be difficult to avoid, as the blood-sugar levels vary widely under constant conditions from day to day, but with careful watching no harm results.

INSULIN AND CARBOHYDRATE BALANCE.

There is no constant insulin-carbohydrate ratio which can be applied to the treatment of diabetes; the amount of carbohydrate which a unit of exogenous insulin will metabolize varies with the internal pancreatic and hepatic activity of the individual and the rate of absorption of

the carbohydrate. When taken in a non-concentrated form in which absorption is slow, as in green vegetables and fruits, the diabetic metabolism aided by exogenous insulin can deal with carbohydrate more efficiently than when the same calculated value is given in concentration, as in starches or sugars; in consequence, diet restrictions remain a fundamental part of the treatment and the carbohydrate is restricted both in total value and in the form in which it is taken. A high total diet with large insulin dosage in a severe case lead to excessive gain of weight due to deposits of fat; and in some cases to a condition resembling oedema; a loss of balance and a return of glycosuria follow. Young patients are particularly liable to this condition, which must be treated by a period of under-nutrition and reduction of insulin. Severe diabetics fattened under the influence of insulin may develop a fatal ketosis should they acquire a septic infection; it seems as though once their large stores of fat begin to break down into ketones no further treatment with insulin and carbohydrate will arrest the process.

ADMINISTRATION OF INSULIN.

Every patient who is not physically incapable should be required to give his own hypodermic injections. Dependence on a doctor, nurse or relative may lead to forced intermission of treatment at a critical time. Local reactions and infections are extremely rare in spite of imperfect technique. No preparation for oral administration has been found hitherto to replace the hypodermic administration.

BLOOD-SUGAR ESTIMATIONS IN DIAGNOSIS AND TREATMENT.

The blood-sugar concentration varies from hour to hour in relation to the taking of food, especially of carbohydrate, and also with exercise; this range of variation is far wider in the diabetic than in the normal, and must be kept clearly in mind. When sending patients for a test to the laboratory the clinician must know what particular point he wishes investigated; haphazard estimations on a patient who is taking a haphazard diet and passing an unknown amount of sugar will give little information which cannot be obtained in other ways.

Tests made under controlled conditions are valuable in certain cases:—(1) For diagnosis; (2) for an estimation of the severity of the disease; (3) for guidance in treatment in respect of diet or insulin; (4) for estimating progress; (5) in ketosis. Fasting tests are usually made, unless for special reasons, and the preliminary fast may be from four hours to twelve hours (overnight), or for a longer period.

(1) *Tests Required for Diagnosis* are not necessary in cases which present the symptoms of clinical diabetes. They should always be made in cases of pregnancy with glycosuria and in cases of doubtful origin where the condition may be due to an endocrine disturbance of thyroid or pituitary or a "renal glycosuria." The fasting estimation in such cases is usually followed by a "sugar-curve," in which the patient is given carbohydrate by the mouth, and the rise and fall of the concentration in the blood is watched for the following two or three hours. "Sugar-curves" are seldom required in true diabetes, and are not advisable in a severe case.

(2) *Tests for Estimating the Severity of the Disease.*—In uncomplicated cases the test should be made after the patient has been under treatment by diet for a week or fortnight and is on a known carbohydrate intake and output as estimated in a daily urine collection. If glycosuria has been abolished by diet it may be discovered that the patient has a raised "renal threshold" for sugar, i.e., when the urine is sugar-free the blood-sugar is above the normal leak-point for sugar, 0.18 gm. per cent. The urine should always be obtained at the actual time of making the estimation to establish this point. The preliminary fast should, if possible, be an overnight fast, the longer periods of fasting, twenty-four or forty-eight hours, are not of value in ordinary

clinical work: the estimation is needed as a guide to the severity of the case and the treatment that will be required, and for that purpose should be made during a period of normal resting metabolism, and not during starvation.

(3) *Tests for Studying the Effect of a Single Dose of Insulin.*—These are sometimes required when the symptoms suggest hypoglycaemia.

(4) *Tests for Studying the General Course of the Disease.*—These may be made at intervals of a few months, but deterioration or improvement will usually be apparent in other ways.

(5) *In Ketosis.*—Tests are invaluable in cases with threatened or developed coma where massive doses of insulin must be given in quick succession. The treatment of coma is outside the scope of this paper.

Reviews.

CINCHONA IN THE EMPIRE, PROGRESS AND PROSPECTS OF ITS CULTIVATION.—By J. M. Cowan, M.A., D.Sc., F.L.S. 1929. Pp. 9. Reprint from the "Empire Forestry Journal," Vol. 8. No. 1. 1929. Price, 6d.

EVERY medical man in India should read this small brochure, for it is a complete exposition of the present position of the cinchona problem, and of very great interest and importance. The author is Officiating Director of the Botanical Survey of India and Superintendent of Cinchona Cultivation, Bengal.

At present at least, quinine cannot be produced synthetically. Yet it is estimated that some 800 million persons are attacked every year in the tropics by malaria, and according to Sir Ronald Ross more than two million deaths occur annually from the disease. The economic loss due to the disease is put down by Dr. Andrew Balfour at between £52 and £62 millions a year.

Prior to 1880 the world's supply of quinine was obtained chiefly from the cinchona forests in Ecuador, Bolivia and Peru, but the plant was then introduced into India and Java, and the story of the adventures and hardships of the early pioneers—Weddell, Hasskarl, Markham, Ledger, and others, is well known. In India the earliest plantations were in the hands of private planters in the Nilgiris, but, as the plant did not prove an economic success, these plantations were uprooted. To-day cinchona is grown in three areas in India, at Mungpoo in the Darjeeling district under the Bengal Government, in the Nilgiris under the Madras Government, and a small experimental station in Burma. The Dutch, however, have gone vastly ahead with a well organised and subsidised official organization; to-day Java supplies more than 90 per cent. of the world's requirements of quinine, and India but 4 per cent. India in fact imports two-thirds of her annual consumption under present conditions.

Such a situation is naturally very unsatisfactory. Sir Patrick Hehir has estimated that the smallest amount of quinine which would have any influence on malaria in India is 970,000 lbs. a year, the present consumption being about one-sixth of this figure. The necessity for vastly increased production of cinchona, and for greatly reducing the present price of £1 9s. 6d. per lb., is therefore obvious. In India it is estimated that the number of deaths from malaria total approximately 1,300,000 a year.

From these preliminary observations, the author goes on to describe methods of cinchona cultivation, and the alkaloidal constituents of the bark. There are no less than sixty-five species of *Cinchona*, but *Cinchona ledgeriana* gives the largest quinine yield. Conditions for cinchona cultivation are peculiar; there must be evergreen forest on granitic or volcanic rock formation. The soil must be rich, porous, well-drained and with moderate to steep slopes. The least water-logging is fatal to the plants. The plant will not withstand either great heat or frost. The limits of rainfall are from 75 to

180 inches per annum; the altitude from 1,500 to 5,000 feet. Forest has to be felled and then burnt; and the seedlings have to be in a nursery for six months before being planted out. Two transplantations are necessary. Harvesting begins about the fourth year, but the richest yield is obtained when the trees are uprooted in the tenth year. The land has then to be allowed to revert to forest for some years before it can be planted again. It will be seen therefore that only certain selected areas in India and Burma are suitable for cinchona cultivation, and the only test as to whether a given area is or is not suitable is an experimental trial on a small plot. The problem of finding suitable land resolves itself into a process of elimination.

The second basic problem with regard to increasing India's yield of quinine is to enhance the output of cinchona per unit of area. This is a matter for scientific research work. Financially, there need be no fear that cinchona cultivation will not pay; "I think it is no exaggeration to state that so far as the material side of the question is concerned" wrote Grassi, "the benefit derived annually from the anti-malaria campaign is sevenfold the value of the money expended."

We trust that Dr. Cowan's little pamphlet will have a very wide circulation in India.

THE RAT, A WORLD MENACE.—By A. Moore Hogarth, F.E.S. Pp. 112, with several illustrations. 1929. London: John, Bale, Sons & Danielsson. Price, 7s. 6d.

WE trust that this compact and most useful book will have a wide sale in India among medical men, public health officials, and even the lay public. The rat is the foe of civilization, but—above all—the foe to-day of India. The book is at once complete, extremely informative, useful for both reference and reading, and very interesting. It is dedicated to the Medical Officers of Health of Great Britain "whose courage and sagacity have saved the administration of an unsatisfactory Rats' Act from being utterly abortive." In an introduction to the book, Sir Thomas Horder, K.C.V.O., F.R.C.P., writes that the book is not merely a standard textbook on the subject, but that it is a model for others who seek to add to the literature on pestology.

Chapter I deals with the history of the rat, and of rat migrations within historical time. The different species of rats and mice are described, and an appendix gives the draft of a Rat Destruction Bill presented to the House of Commons (but not passed) in 1919. In Chapter II the habits of the rat, and its amazing fecundity are discussed; the section is full of detailed, and often novel, information. Rats commence to breed at 3½ to 4 months of age, and the ordinary litter recurs about four times a year and consists of about six or seven young. Four pairs should produce about 10,934,590 young in ten years, whilst the progeny of a single pair in ten years, under absolutely favourable circumstances, might amount to the appalling total of 48,319,698,843,030,344,720, which would leave no room upon the globe for any other form of life. Fortunately, as in all forms of life with extreme fecundity, the mortality is almost equal to the production of young.

In general, the rat population for any given area may be assumed to be about ten times the human population. In other words, the total consumption of foodstuffs by rats in Great Britain may be roughly put down at £100,000,000 per annum. Not only is this the case, but the damage to valuable libraries, pictures, tapestries, and other works of art is perhaps almost as important. The United States are said to spend \$1,825,000,000 yearly in feeding rats.

Turning to human diseases spread by rats, plague of course comes first and foremost, as we know too well in India. The connection of the rat with epidemic leptospiral jaundice is also well known (though here perhaps it is rather a case of both man and the rat becoming mutually infected from contaminated water supplies; yet there can be little doubt that the dead bodies of such rats may contaminate a water or food supply). Trichiniasis is a third example of a rat-borne disease,

rat-bite fever (a quite common disease in India) a fourth example. (It seems rather a pity in this connection that the author appears to have consulted no literature more recent than that of 1919; there has been much more recent work on the disease.) *Hymenolepis diminuta* infections are also rat-transmitted, and meliodiosis, a glanders-like disease, is also suspected of such transmission. On pp. 31 and 32 is given an imposing list of the natural ecto- and endo-parasites of rats, protozoal, helminthic, entomological and bacterial.

Of natural enemies of the rat, the cat comes first, but is usually too well fed and looked after to be of much use. The barn owl and kestrel are probably more useful. The author discusses the Rodier system; this suggests the universal trapping of rats; that all captured females should be destroyed, but all captured males again let loose. If by this means the natural excess of females over males were to be replaced by an excess of males over females, the rat population would destroy itself. The method is of great interest as a suggestion of a method of biological control, but, we fear, impracticable in practice.

Chapters on how to kill rats, flooding and smoking, ferreting, and trapping, follow. The last is of special value, and the value of almost every different type of trap is discussed, also when to use them and when not. Chapter X deals exhaustively with rat poisons. Very numerous prescriptions are given, and details on how to prepare and lay baits. Virus control is then discussed; this has been put forward chiefly of recent years by the researches of Jensen in Copenhagen. Most viruses at present in use are harmless to animals other than rats, whilst Raebiger in 1928 in Germany claims that 98.6 per cent. of village, town and farm plots had been freed from rats by the extensive use of virus. Details are quoted on p. 83 of the book.

Further chapters follow on the special measures necessary to deal with rats in different situations, in farms and outbuildings, in factories and warehouses, in sewers, and in ships. There is here much sound writing and useful, detailed, advice. Suggested measures—largely of legislative type—are discussed, and a final chapter on deratisation concludes the book, and includes several quotations from the daily press. The volume is not indexed.

The Rat, a World Menace is a book which should make a very special appeal to medical men in India. At present our measures against the rat in India are but half hearted, whilst the killing of even such a pest as the rat is discouraged by religious prejudice. Education, above all, is necessary, and in this volume the public health propaganda worker, the special plague officer, and the general medical worker in India will find much of both interest and importance. It is well written, commendably brief, and well published. We hope that it will be appreciated by a wide circle of readers in this country.

R. K.

THE WRITING OF MEDICAL PAPERS.—By Maud H. Mellish-Wilson, Editor of the Mayo Clinic Publications. Third edition, revised. Pp. 184. 1929. W. B. Saunders Co., Philadelphia and London: Price, 7s. 6d.

Doctors may excel in their own profession, but, almost without exception, they are very bad authors. An article submitted to a medical journal for publication should be brief, well written, succinct, and ready for press with but a few slight alterations. Yet, in the case of this journal at least, the majority of papers received and published have not merely to be corrected, but re-modelled and re-written. We can wish ourselves no better fate than that every one of our regular contributors should buy a copy of this small and most useful little book, and study it. Apart even from the question of style, there are certain usages in scientific publications, such as the methods of constructing a bibliography, which the medical profession badly needs to learn. "The artist uses whatever material and whatever forces he

finds at hand, but he does not allow himself to be mastered by them. And when he has finished his work, he does not fall down before it. He looks at it critically, he sees its limitations, and he plans a new work which he hopes may surpass it," quotes the author from Crothers.

The subject matter of the book is arranged in two parts, the first seven chapters being devoted to technical details, and the last thirteen to general instructions. Good usage, vocabulary, the use (and misuse) of italics, the use of abbreviations, the construction of tables, punctuation, grammatical notes, and a splendid chapter on "don'ts" comprise the first part. Then come chapters on arrangement, the preliminary drafted outline of the paper, construction, case histories, references, revision, title, and volume of output.

The last named subject is all-important. Mr. Clifford Dobell, F.R.S., once told the reviewer in conversation that his criterion of the value of a medical paper was whether it would be either read or consulted a hundred years hence. Judged by such a standard, nine-tenths of present-day medical literature might well be sieved out, and the grain separated from the chaff. To quote the author of this book "many of the journals now in existence are a discredit to the profession, and there is also the deplorable fact that their doubtfully valuable contents must be included in our already overcrowded indexes." To publish twelve papers a year should constitute professional malpraxis, and there are authors who write far too much and far too frequently.

The succeeding chapters deal with the manuscript, the proof, quoted material, and the index. A most valuable list of the standard abbreviations for medical journals occupies 48 pages, and a good index completes the volume.

Everywhere the instructions are clear, well expressed, and admirable. Each chapter commences with an apt quotation, and ends with *obiter dicta*. This valuable little book has gone through three editions in seven years. We can express our appreciation of it best by hoping that it will see many more editions, and that it will make a special appeal to our contributors. Surely it is not too much to ask of the author who sits down to write a paper for publication that he should make a preliminary study of style and good usage.

One of our chief difficulties in India, which the author has not encountered in America, is the "capitalist." The Indian typist cannot keep away from capitals; for example if the paper deals with malaria, this word is always written Malaria. A second special difficulty in India is the abbreviationist; he will invariably write pt. for patient, m.p. for malaria parasite—whereas it might just as well stand for military policeman; and T. B. for tuberculosis.) If we can remember to do so, we promise to send the author of this book a typical script, as received by us, after correction. She might decide to incorporate a page of it in her next edition as an example of "how not to do it"!

R. K.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY.—By W. A. Newman Dorland, A.M., M.D., F.A.C.S. Fifth edition (1929), revised and enlarged. Pp. 1427. Profusely illustrated. Philadelphia and London: W. B. Saunders Co. Price, thumb Indexed 37/6; plain 35/-.

We have reviewed previous editions of this invaluable work. It is not a "dictionary," but an encyclopædia; in brief it is almost the medical *Encyclopædia Britannica* for the physician and medical author and editor. It is admirably printed, profusely illustrated, extremely well bound with a limp morocco binding.

In its present edition this most valuable work has received the most thorough revision of its long career, dating from 1901. A large corps of associate workers has combed the literature of the two years since its last new edition in 1927, with the result that several thousand new terms have been added. Careful revision has been given to the wording of every definition in the work. The terms in anatomy, pathology, physiology and physical therapy have received special attention. A

definite standard has been adopted in terminology, spelling, hyphenization, etc.

The entire book has been re-edited by the editorial staff of the American Medical Association, whilst Dr. E. C. L. Miller, Professor of Bacteriology and Biochemistry in the Medical College of Virginia, has collaborated with the author in the revision. The new edition has been reset from new type, and many illustrations added. That it is very fully up-to-date is obvious from a perusal of its pages.

The standard spelling adopted is, of course, American, rather than British. Under *factus*, for instance, we are referred to *fetus*; under *Entamaba*—synonym, *horribile dictu*, *Entameba*—to the still worse *Endameba*. These violations of etymology are inherent in the American language; and the English reader can only be grateful that the older and more correct forms are still given for reference. It would be easy, but unprofitable, to try to pick holes in what is a splendid and invaluable work of reference.

The arrangement is excellent, and the illustrations—especially the full page colour plates—are very good. We are sorry that opposite p. 953 the colour plate of the malaria parasites still shows these important organisms in their unstained condition; surely such a method of examination is now never practised in the tropics; and a new plate showing the appearance of the parasites in Romanowsky stained films is wanted. *Plasmodium kryptoplastikon* is new to us; it is Schiller's supposed protozoal protozoan parasite of cancer (and might well be left to disappear into obscurity).

These very minor criticisms do not in any way detract from the sterling value of this monumental work. A copy of the new edition should be in every medical library in India. A specially valuable feature of the work is that pronunciations are given throughout, and also Greek derivations; this adds very greatly to the value of the work.

R. K.

REPORT OF THE SEVENTH CONGRESS OF THE FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE. British India. Dec. 5th-10th-24th, 1927. Calcutta, Government of India Press, 1929.

THE full *Transactions* of this Congress are in course of publication, and Vols. I and II of these *Transactions* have already appeared, and have been reviewed in our columns.

The present small volume, however, is different. It is a summary of information connected with the Congress, and most useful for reference, and to gain a general idea of the Congress. No price is mentioned, but we presume that the volume is obtainable from the official agents for government publications.

The book opens with a list of officers of the Congress and Council; then follows a brief and useful resumé of the proceedings of the Congress, with abstracts of papers and discussions. The opening addresses are given verbatim, and the agenda and minutes of the official business meetings. An account of the different tours made by foreign delegates in India comes next; then the report of the committee on beriberi, Philippine Islands. A complete list of members of the Association occupies some sixty pages; and will be found most useful for reference. The volume closes with the articles and by-laws of the Association.

We have dealt in such detail with this Congress that we need not further dilate upon the present volume. It will be found generally useful, both for reference, and as a resumé of the Congress.

BRONCHIAL ASTHMA—ITS DIAGNOSIS AND TREATMENT.—By H. L. Alexander, A.B., M.D. London: Baillière, Tindall and Cox. 1929. Pp. VII plus 171 with 8 figures in the text. Price, 10s. 6d. net.

THE subject of asthma has been approached from so many viewpoints and such an enormous amount of literature has grown around it, that it is indeed difficult for an average medical man interested in the subject to form a clear idea of the main issues involved. The various

causative factors, be they infection, psychic disturbance, nasal irritation, allergy or mechanical irritation of the bronchi, have been stressed by various authors with so much warmth and emphasis that a broad conception of the subject—that it is something more than an effect resulting from a single process—is seldom fostered in the minds of the readers. "Bronchial Asthma," by H. L. Alexander, presents the problem of asthma in a crystallised and condensed form and hence may be expected to make a strong appeal to the minds of medical men. The handy size of the book (a monograph of about 160 pages) is another point in its favour. Without attempting to enter into minute details, the lines of treatment have been admirably indicated. The appendix at the end of the book lays down the common diagnostic methods, and the bibliography at the end of each chapter gives valuable references.

R. N. C.

THE EYE IN GENERAL MEDICINE.—By Dr. Meland Ramsay, M.D., LL.D. Second Edition of *Diathetic and Ocular Diseases*. London: Baillière, Tindall and Cox. 1929. Pp. X plus 255. Price, 12s. 6d. net.

THIS is the second edition of the author's "Diathesis and Ocular Diseases," and has been entirely re-written and re-arranged and is now published under its present name. The book is not a systematic textbook of ophthalmology, but a personal record of the author's long clinical experience of morbid conditions of the eye in relationship to general disease. The contents consist of ten chapters which are complete in themselves on various diseases in which the eye plays an important part. The author points out how essential it is to bridge over the gap between specialism and general medicine. The principles of general physiology are sufficiently broad to include every organ of the body and it is the same physiological and pathological processes which are at work. The ophthalmologist must be first and foremost a doctor, familiar with general medical principles, and must realize that the cause of the disease is not necessarily to be found in the organ manifesting the symptoms, and no treatment can be successful until the cause underlying the disease has been discovered and removed. General medicine owes much to ophthalmology, and how often in one's clinical experience have signs of serious general disease been discovered by lesions in the eye such as diabetes, nephritis and cardio-vascular disease, and it is important that the general practitioner should have a knowledge and take an interest in the diseases of the eye.

The author is dogmatic in his teaching and presents his articles in a clear and convincing fashion and written in a simple style. The book makes very delightful reading and will prove of great interest not only to the ophthalmologist but to the general practitioner. We cordially recommend it to our readers.

E. O'G. K.

SKIN: ITS USES IN SIX PHASES.—By Lewis E. Hertslet. London: J. & A. Churchill. 1929. Pp. XVIII plus 206. Illustrated. Price, 10s. 6d. net.

THIS book has been written by an enthusiast obsessed with the value of light as a curative of all diseases. Unfortunately in the tropics we often suffer from the effects of too much light, and there is a well known Arab proverb that only Englishmen and fools prefer the sunlight to the cool shade.

In spite of the enthusiasm of the author, the book contains a mass of facts dealing with the skin from the different aspects. The work has been written from the popular point of view, and should appeal to those who are interested in this subject.

H. W. A.

ON PRESCRIBING PHYSICAL TREATMENT.—By Matthew B. Ray, D.S.O. M.D. (Edn.), London: William Heinemann (Medical Books) Ltd. 1929. Pp. IX plus 179. Illustrated. Price, 10s. 6d. net.

THE author states in his introduction that "This book is written entirely from the standpoint of the prescriber, and is not intended to be anything in the nature of a

technical handbook. There are many of the latter in existence which fill their purpose so well, that an addition to their number would be superfluous. Such works have been written by specialists in electro-therapy and kindred sciences, and are not intended for the busy practitioner, who has neither the time nor the inclination to sift out what is, to him, a vast amount of irrelevant information, in order to find the clear cut directions which he wishes to embody in his prescription."

With this point of view the reviewer is at variance, because of the danger involved to the patient by such a procedure. To relegate the practice of physical therapy to that of allopathy, and for a physician who is not specially qualified in the subject to prescribe in "clear cut directions" the treatment to be given to one of his patients by one qualified to do so, is as absurd as it would be for a physician to indicate to his surgeon the proper way to make the operation required. It is not at all to be commended.

However, in spite of this, the work is to be recommended, because within 179 pages the writer gives a valuable bird's-eye view of the subject, which is at least interesting reading for the spare time of a general practitioner. There are 6 plates and 7 illustrations in the text.

C. G. R. M.

AIDS TO DERMATOLOGY AND VENEREAL DISEASES.—By R. M. B. MacKenna, M.A., M.B., B.Ch. (Camb.), M.R.C.P. (Lond.), M.R.C.S. (Eng.). London: Baillière, Tindall & Cox, 1929. Pp. VIII plus 236. Figures in the text 7. Price, 3s. 6d. net.

THIS book is a very useful primer, and should be used as an introduction to the subject of dermatology. The book is well written and the lines of treatment are brief and to the point. In this country where dermatology is not taught in the medical schools, the practitioner would be well advised to get this book to study before advancing to the larger textbooks on this subject. We can confidently recommend it to our readers.

H. W. A.

RADIUM AND ITS SURGICAL APPLICATION.—By H. S. Souttar, D.M., M.Ch. (Oxon.), F.R.C.S. (Eng.). London: William Heinemann (Medical Books) Ltd. 1929. Pp. VII plus 60. Illustrated. Price, 7s. 6d. net.

THOUGH radium as a therapeutic agent has been known for many years there has been a lamentable lack of a clear exposition of its uses, and the results obtained. There is probably due to the fact that in many cases its use is still in the experimental stage, and few have been found with courage sufficient to publish their results. This volume, therefore, is very opportune, for here we have the subject dealt with in 60 pages in such a lucid manner that a medical practitioner will have not only no difficulty in following the author, but also will positively enjoy reading him.

The author first of all deals with the physics of radium: next the apparatus and means of application, then the sensitivity of the tissues to radium, and proceeds to deal with malignant growths in various situations, which are suitable for radium therapy.

The reviewer, from his own experience, can corroborate the views of the author, and would draw particular attention to the following cases cited by the author:

"A man of 53 had complained for three months of epigastric pain, increased by food, of loss of appetite, and of loss of weight which he estimated at 2 stones. On exploration a firm, smooth oedematous tumour of greyish colour was found involving the lesser curvature, and extending upwards almost to the cardiac orifice. It was regarded as a carcinoma of a rapidly growing type and it was obviously inoperable. There were, however, no enlarged glands." It was decided to treat the case with radium, and there follow details of the procedure adopted. The result was as follows:—

"The patient made a normal recovery, his pain ceased, his appetite returned, and in three months he had

regained his normal weight and was a picture of health. Nine months after the operation he has had no return of symptoms."

"A man of 72 had suffered from increasing difficulty in swallowing for three months and he could now only swallow sips of water with great difficulty. A tall, powerfully built man, he had lost 3 stones in weight and he was so weak that he could scarcely stand. An x-ray film showed that the œsophagus was obstructed by a malignant growth 10 inches from the teeth. On œsophagoscopy a large ulcerated mass of growth was seen encircling the œsophagus, bulging prominently inwards on the left side." There then follow details of the radium treatment adopted. The result was as follows: "In 24 hours there was a distinct improvement in swallowing, which may, however, have been due to the passage of a bougie at the operation. In a week he was taking ordinary soft foods, and was obviously gaining weight and strength. In 4 weeks he was taking an ordinary full diet, with the sole precaution that he should eat slowly. In 6 weeks he had gained nearly 2 stones in weight and appeared to be in perfect health."

As the author proceeds; "These are typical examples of our experience in a considerable number of cases, and although we are not so optimistic as to expect that recurrence will not take place, after following most of them for several months we feel that they are a considerable advance on any results we have previously seen."

Again the writer can corroborate from personal experience, and, if anything, the author has understated the claim of radium as a miracle worker in apparently hopeless cases.

This little book is thoroughly sound in all points, and has the merits of lucidity and brevity so rarely met with in dealing with so abstruse a subject as radium. It stands on its own merits and is to be recommended to all interested in their profession.

C. G. R. M.

ESSENTIALS OF MEDICAL ELECTRICITY.—By E. P. Cumberbatch, M.A., B.M. (Oxon.), D.M.R.E. (Camb.), M.R.C.P. Sixth Edition. Revised and Enlarged. London: Henry Kimpton. 1929. Pp. XVI plus 443 with 11 plates and 116 illustrations. Price, 10s. 6d. net.

THE sixth edition of this famous work is to be welcomed by all interested in the subject. The present volume is changed in size and format, with considerable improvement in both type and paper. Dr. Cumberbatch's name is well known as perhaps the greatest authority in medical electricity in England, and the present volume amply retains his high prestige, for not only does he deal with the matter theoretically and scientifically, but also practically, to the great benefit of both the student and the operator. In fact, it may be stated that anyone who has thoroughly mastered the contents of this book, has knowledge sufficient for the management of the majority of cases requiring electrical treatment. There are in all 18 chapters, each complete in itself, dealing with the various aspects of the subject. One particularly valuable chapter is the Index of Electrical Treatment (Chapter 18). This should certainly be read by all practising physicians and surgeons, for it reveals the scope of this form of therapy in lucid and brief words.

This work is recommended to all interested in the subject, as one of the clearest expositions of it known to the reviewer.

C. G. R. M.

METHODS AND PROBLEMS OF MEDICAL EDUCATION (12TH SERIES).—By R. M. Pearce, Director of Medical Sciences, The Rockefeller Foundation, New York, U.S.A. Pp. 466. Illustrated.

ANY publication from this source well repays the time spent in its perusal. This volume is certainly up to the usual high standard.

One of the main difficulties in medical education is the difficulty of knowing how the problem one is concerned with, is being tackled in other countries. Perhaps there is no sphere of the subject more open to this than that of radiology, for it is seldom that anyone, with both

the experience and judgment necessary for such a task, can be granted more than a month's leave a year.

Consequently, this volume, which contains the personal report of 39 Chiefs of Radiological Departments, representing 11 different countries, is particularly valuable to anyone in control of either a teaching centre or an X-Ray Department. There never has been collected together, until now, between two covers, articles written by such famous names in radiology as A. E. Barclay, Guido Holzknecht, Preston M. Hickey, Robert Knox, J. Magnus Redding, and Friedrich Dessauer, etc. All of them make stimulating reading and it is difficult to single out articles for special consideration.

The considered exposition of the subject by Holzknecht should, however, be read by all practising the art of medicine in whatsoever sphere, for here there is a fearless declaration of both the scope and limitations of radiology. Another article that all interested should read, perhaps the best in the book, is that of A. E. Barclay on the Organization and Equipment of an X-Ray Department.

The illustrations are ample and very adequate for the difficult subject they portray, and show the diverse ways in which different people have approached the same subject. There is a good index, and the quality of the paper is good.

In conclusion, this is a work well worthy of the great institution which produced it, and great praise must be given to the editor and his staff for its production.

C. G. R. M.

SNAKES OF AUSTRALIA.—By J. R. Kinghorn, C.M.Z.S., with a Foreword by H. A. Longman, F.L.S. Australia: Angus and Robertson, Ltd. 1929. Pp. 198 with 137 drawings, photographs and text-figures. Price, 10s. net.

This book is a very useful guide for the recognition of the common poisonous snakes of Australia. The illustrations are very well done and in colours, which helps to make the recognition of these reptiles an easy matter. A key is given at the beginning of the section to identify the common genera and species. A book on similar lines illustrating the snakes of India is very much needed for the use of medical officers and other workers in the mofussil.

H. W. A.

Annual Report.

REPORT OF THE HAFKINE INSTITUTE, BOMBAY, FOR THE YEAR 1928. BY MAJOR, S. S. SOKHEY, I.M.S., OFFG. DIRECTOR. BOMBAY, GOVT. CENTRAL PRESS. PRICE, 6 PIES.

The Haffkine Institute, with its admirable laboratories, large staff, and spacious grounds, is in a particularly favourable position for medical research work, and its annual report is always of interest. We cannot do better in reviewing it than to quote Major Sokhey's general review of the year, which is as follows:—

Plague Vaccine.—During the current year about two million doses of Haffkine's Plague Prophylactic were sent out; this is a considerable increase on the last year's demand. The United Provinces of Agra and Oudh and the Punjab are still the largest consumers.

The process of manufacture of the prophylactic has remained unaltered. But the discovery by Dr. Goré of the fact that blood agar is the medium of choice for the growth of *B. pestis* has enabled us to detect with greater certainty contaminating organisms in the prepared vaccine, and thus secure greater purity of the finished product. Dr. Goré has found that the growth of *B. pestis* is more profuse on blood agar than on nutrient agar. If dilutions of broth culture of *B. pestis* are made, a point is reached when the dilution planted on nutrient agar shows little or no growth, while blood agar shows numerous colonies. This dilution in the case of six weeks'

cultures of *B. pestis* in broth—Haffkine's Prophylactic—is roughly 1 in 1,000. A small quantity of culture to be tested is diluted as indicated above and is planted on blood agar and nutrient agar. If after 48 hours incubation the agar slope shows any growth at all, contamination is suspected and further exhaustive tests are made.

This test is now being used as a routine measure for testing the purity of the seed cultures and the fully incubated vaccine. Until this test was introduced, besides the sugar reaction, the purity was judged by the appearance of agar slopes planted with undiluted cultures. The slopes were incubated for 48 to 72 hours, and if they presented a ground glass semi-translucent appearance they were taken to indicate pure plague cultures; moreover in the sugar test *B. pestis* was expected to ferment without the production of gas, glucose and mannite only. We now know the ground glass appearance of the agar slopes does not necessarily indicate pure *B. pestis* growth. Some contaminants, especially a Gram-positive coccus, escape detection, because they in no way disturb the so-called ground glass appearance of the agar slopes. Those common contaminants produce no change in the sugars, and so again escape detection. All these organisms are easily detected by the present blood agar test. If any growth appears on agar slopes it raises a suspicion of contamination, and the examination of discrete colonies which are regularly obtained on blood agar decides the point.

Making use of Goré's blood agar slopes, Major Sokhey and Dr. La Frenais made a number of quantitative determinations bearing on the manufacture of Haffkine's prophylactic. They have found that a wide range of pH of the medium gives good growths of *B. pestis*—pH 6.2 to 7.4, with a slight advantage in favour of 7.0. In the broth ordinarily used for the preparation of the prophylactic the growth of *B. pestis* comes to an end at the termination of three weeks. The addition of $\frac{1}{2}$ c.c. of rabbit blood per 10 c.c. of broth makes the growth much more profuse than that in broth without blood. It was also found that although the growth is profuse, it loses its virulence rapidly. After about 40 subcultures in blood broth, each of 48 days duration, 40 million organisms failed to kill rats, where the 50 organisms of the original growth in nutrient broth killed cent. per cent. of the rats.

Major Sokhey and Dr. La Frenais also investigated into the validity of the routine test in use for testing the immunising powers of the various brews of the prophylactic manufactured. The results of duplicate tests on the same brews varied sometimes by 300 per cent. and more, and showed that the test had no value as a measure of the immunising properties of the prophylactic. They found the test dose of 0.003 mg. of plague-spleen used in the routine test was a very variable quantity as far as the number of plague bacilli contained in it went. An actual count of seven test viruses made and used by Dr. Naidu in his work showed that the number of organisms in 0.003 mg. of his test virus spleen varied from 120 to 46,000. In place of the routine technique 23 experiments were performed with 11 brews, using a test virus containing organisms between 490 and 1,000. The results of duplicates were much closer together, but still the variation was great enough to render the test valueless. Work on the question is still proceeding. It is proposed to place this work before a committee of experts to recommend some minor changes in the manufacture of the plague prophylactic.

Parasitology of Plague.—The Plague Expert Committee of the Health Organisation of the League of Nations at their first session in Calcutta in December 1927 laid down the lines of future research in plague and they laid stress on the "Investigation into the comparative epidemiological rôle of the various species of fleas in plague transmission in selected areas of India." This investigation was taken up by Major Webster and Dr. Chitre in August, and the work is still proceeding. But it may be mentioned that up to now they have secured successful transmission experiments with all the three species of fleas found in Bombay, i.e., *Xenopsylla cheopis*, *X. astia*, and *X. brasiliensis*. The successful transmission

with *X. brasiliensis* is interesting as this species has not previously been proved to be a vector of plague in India.

Anti-plague Serum.—The work by Dr. Naidu and his assistants reported last year has been continued during the year. Following on the successful experiments in the production of a potent anti-plague serum in rabbits; calves and sheep have been selected as the experimental animals to obtain larger quantities of the serum. The work is proceeding, and the results obtained so far are promising.

The Pharmacological Department.—Work on the chemotherapy of plague has been continued. Two classes of drugs are claiming the attention of the department:—(1) the three dihydroxybenzenes—catechol, resorcinol, and quinol, and (2) mercurated phenols and mercurated amines. Forty-eight mercurial compounds have been synthesized and the department is now directing its attention to animal experiments. The work is not sufficiently advanced yet to record any results.

The indigenous drugs section has been studying *Garcinia mangostana*, *Terminalia* sp., and *Gymnema sylvestre*. These investigations are of scientific value; but those who expect the immediate discovery of wonderful therapeutic agents in large numbers to replace the remedies in use at present are sure to be disappointed. Investigations into the nature of indigenous drugs is a problem which involves much time and labour. It is a matter of regret that the pharmacological department is understaffed.

The Biochemical Department.—Researches in anaemia by Major Sokhey and his assistants have revealed the great prevalence of anaemia resembling pernicious anaemia among men and women in Bombay. Their studies show that anaemia of sprue and of pregnancy have a great resemblance to pernicious anaemia, and they believe that the so-called anaemia of pregnancy is not a distinct entity, but merely an aggravated condition of anaemia commonly present in non-pregnant women.

The work on basal metabolic rate was continued during the year and results tend to show that the average rate for India is about 10 per cent. lower than that for Europeans. This they are inclined to believe is due to climatic factors in the widest sense of the term.

The department is also establishing normal standards for various substances usually investigated in diagnostic medicine in the chemical analysis of blood and urine. The department was also engaged on some problems connected with the manufacture of plague vaccine as noted above. Besides the research work the department has proved of value in aiding the more advanced physicians in their diagnostic work. It is now practically impossible to practice modern medicine without the aid of biochemical analytical work.

The Antirabic Department.—The statistical figures for the department given in the body of the report show that the value of the antirabic centre is well understood by the public, and that full use is made of the centre. Against 718 persons who received treatment, 458 persons reported here who did not need any antirabic treatment. They were advised regarding keeping the offending animal under observation, and their wounds were dressed.

Thorough disinfection of the wounds was carried out as a routine measure in the treatment of all cases who reported for treatment within a reasonable time after injury. The death rate among patients so treated was 0.43 per cent. as compared with the death rate of 1.63 per cent. among patients not so treated for various reasons.

It is to be regretted that the majority of the out-centres which receive antirabic vaccine from this Institute have not furnished statistical returns for the treatments carried out by them. They should realize that antirabic treatment has not reached finality and that it is still in an experimental stage. Unless accurate records are kept of all the cases treated, and statistical returns supplied, efforts at the improvements in the treatment are hampered.

Researches on Sprue.—A comprehensive study of this disease, started by Col. Maekie and his colleagues in 1923 and resumed in 1925, was brought to a close this

year when Col. Maekie left the Institute to take up the appointment of Officiating Public Health Commissioner with the Government of India. The broad conclusions arrived at by these researches were summarised in the last report and most of the papers foreshadowed have either appeared during the year or are in press.

Enquiry on Maternal Mortality in Childbirth.—The investigation was continued throughout the year. Dr. Balfour was on leave from March to October, and her place was taken by Dr. Milne. In October the staff of this enquiry was strengthened by the employment of Dr. Lucy Wills. Dr. Milne and Dr. Mehta continued the routine examination of cases of anaemia of pregnancy and also carried out a series of animal experiments. *B. welchi* has been considered by some to be the possible etiological factor, but the animal experiments done here give no evidence to that effect. Nor do animal experiments with streptococci give evidence that this organism is of any etiological significance.

Dr. Wills has studied 50 cases of anaemia of pregnancy, and four non-pregnant cases with a similar blood picture. She finds the blood counts and pictures of the two categories to be similar. Free hydrochloric acid was present in almost all cases, and they all responded to liver treatment equally well. Dr. Wills has reason to believe that the so-called anaemia of pregnancy is not a pathological entity. The macrocytic anaemia, evidently quite common among the women in Bombay, is made worse by the strain of pregnancy. Dr. Wills is also inclined to the view that this type of anaemia very likely is a deficiency disease, and she is taking up animal experiments to test this hypothesis.

Tuberculosis Enquiry.—At the end of August this enquiry, under the charge of Dr. Soparkar, was transferred from Kasauli to Bombay. Dr. Soparkar and his assistants have been engaged in an investigation of the nature of organisms causing the surgical type of tuberculosis in human beings. This type of disease is known to be caused by the bovine bacillus, but in India they have come across only one case out of a series of more than 65, which was due to the bovine bacillus.

Their preliminary experiments with B. C. G. have not borne out the claims made for its immunising power. They are also carrying on experiments upon transformation of tubercle bacilli of one type into another, but they have arrived at no conclusions yet.

The Indian Research Fund Association.—The cost of the plague, anaemia, maternal mortality and tuberculosis enquiries, amounting to Rs. 1,37,677, was borne by the Research Fund Association. In future years the situation as regards grants from the Association is likely to be altered radically. The Fletcher Committee which was referred to in the last year's report, has recommended the establishment of the Central Research Institute at Dehra Dun, and the Rockefeller Foundation has decided to build the Public Health Institute at Calcutta.

So the position is that Bombay is to receive no aid from any outside agency to help it to make provision for post graduate-training in tropical medicine or public health and hygiene. Bombay is as important a centre of medical education as any in India, but its promising graduates must continue to go elsewhere to complete their training in tropical medicine. Calcutta has a flourishing School of Tropical Medicine and will soon have a first class Institute of Public Health and Hygiene; while Bombay has neither. One School of Tropical Medicine is not enough for the whole of India, and it is high time for Bombay to make provision for itself.

It is a melancholy fact that Bombay is making no headway in providing for research work in medicine. So far all the research carried on at this Institute has been subsidised by the Research Fund Association, and had it not been for substantial help from that Association the Pharmacological and Biochemical Units of this Institute would possibly not yet be in existence. Should the Research Fund Association stop their contributions, most of the research work now in progress will have to be abandoned, with little hope of being resumed in the near future.

The atmosphere of co-operation and cordiality, so essential for scientific endeavour, was maintained without blemish by the staff. The acting director received unstinted and loyal support of his colleagues which made his work easy and profitable.

Correspondence.

RADIUM IN INDIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—It is a matter of great regret that no central agency exists in any large city in India, capable of carrying out radium treatment on modern lines and of supplying radium emanation to other localities. This state of affairs places the surgeon in a helpless position as regards the treatment of many inoperable malignant growths, such cases being handed over to the not very tender mercies of opium and other drugs.

The question is really one which should be taken up by the Government or a Central Committee as an extension of the British Empire Cancer Campaign, or as an independent movement. It is only in this way that adequate funds could be raised.

Australia provides an example of beneficent energy in this direction. The University of Sydney raised £7,000 for cancer research in 1921. The sum was found to be quite inadequate, and a further £134,000 was collected by a public appeal. With this money research was started in earnest. In 1927 the Government of the Commonwealth sanctioned £100,000 for the purchase of radium, and a Cancer Research Committee now exists and is able to produce a journal to publish its activities and stimulate research.

Surely something of the sort is possible in India where vast sums of money are expended by wealthy individuals in vicarious charities. Any large-hearted attempt to advertise the crucial importance of the early recognition of cancer would alone save many thousands of lives yearly. A small Radium Institute exists at Patna, greatly to the credit of the Government of Bihar and Orissa, but this is a mere speck in the ocean when one considers the size of India. In other places small amounts of radium exist, but are only available in a very restricted sense. Perhaps nothing short of three radium centres would be sufficient to cope with the great demand which would soon arise, but one efficient centre would first be needed to gather experience and give an idea of the probable cost of the larger undertaking.

In Calcutta the radium facilities are most lamentable for a great city. What little radium is available is doubtless utilized to the greatest advantage, but a much larger supply is needed, together with a supply of skilled workers for the distribution of radium emanation for the cure of suitable cases.

Recent advances in the technique of radium administration, especially the various methods of deep and intimate burying of radium-charged needles next to the growth by the help of surgery, have done much to revive confidence in this method of treatment. Some of the recently published results have been wonderful, but time alone will show whether the cure is always permanent.—Yours, etc.,

FRANK POWELL CONNOR.

CALCUTTA,
9th December, 1929.

PROLAPSUS UTERI.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I write with reference to Captain Variava's article on "Wertheim Sehanta's interposition operation for complete prolapse of the uterus" and your note thereon in the December number of the Gazette.

Lest it be imagined that this is a new operation, I should like to point that it is thirty-one years old. I quote from Graves's *Gynaecology* (1923), page 229:—"The Watkins' interposition operation for prolapse and procidentia. The principle of the Watkins' operation

is based on separating the bladder from the anterior wall of the uterus and transposing its attachment to the posterior wall, so that the uterus is left in a position to support the entire bladder. Watkins performed his first operation in 1898. Several modifications, notably that of Wertheim, have appeared since."

Devoting six pages to the details and illustrations of the operation, he adds on page 836, "Wertheim described an operation in 1899 similar to that of Watkins and based on the same mechanical principles."

I frequently saw the operation performed when I was a student—over twenty years ago; it seemed to fall into disuse later and is now only barely—if at all—mentioned in English textbooks. American books, such as Kelly's or Graves's, describe it fully. In the latter there is a word of warning, "The interposition operation has numerous disadvantages, among which are the preclusion of further child-bearing, the persistence of bearing-down symptoms that often follow it, the frequency of bladder symptoms, and the difficulty of the situation if the operation turns out to be a failure."—Yours, etc.,

S. A. McSWINEY, M.B., F.R.C.S.I.,

18th December, 1929.

ANTI-PLAGUE VACCINE IN THE TREATMENT OF PLAGUE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In the recent epidemic of plague at Raichur, almost all cases which I saw were of typical bubonic type, with typical symptoms, the bubo usually being in the femoral region. As the therapeutic value of intravenous injections of iodine in this disease has been recognized by previous workers, I used it as a routine measure, giving injections containing from $\frac{1}{4}$ to $1\frac{1}{2}$ grs. In spite of these injections most patients showed severe constitutional disturbances within 48 hours of commencing treatment, with delirium and restlessness. Severe asthenia would set in about the third day of treatment, and the prognosis was bad. In my experience intravenous iodine, whilst of value in cases seen on the first day of disease, is of little value when a state of severe toxæmia has occurred. The ordinary principles of treating toxæmia, such as surgical treatment of the primary focus of infection, saline infusions to dilute and eliminate the toxins, and specific antitoxic sera or vaccines are now indicated.

After arriving at this conclusion, I was called upon to treat an elderly Mahomedan male, over 50 years of age, of weak constitution. Headache and vomiting were present, with a femoral bubo, and toxic delirium set in within a few minutes of my seeing him. As I understand that the clear supernatant fluid which separates when Haffkine's anti-plague vaccine is allowed to settle contains immunising principles, I administered 2 c.c. of the vaccine diluted with 8 c.c. of normal saline intravenously. Within quarter of an hour there was high reactionary fever with rigor, but an hour later there was great relief of symptoms. Consciousness was regained, and the patient passed urine, which he had not done for several hours previously. I then gave an intravenous injection of iodine, and the patient made a dramatic recovery within 24 hours of first commencing treatment.

As this case occurred towards the end of the epidemic, I had no further opportunity of testing the method on other cases. I conclude however that the value of intravenous iodine is chiefly confined to cases seen within the first 24 hours of onset of the disease; that intravenous injections of anti-plague vaccine may be of value for cases seen at a later stage; whilst blood transfusion from donors who have recovered from plague, though a measure which suggests itself, is one which it is difficult to adopt during an epidemic.—Yours, etc.,

A TEST FOR CARBON TETRACHLORIDE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the "Notes on the use of Carbon Tetrachloride" by Dr. S. C. Nag in the December 1929 issue of your journal, the following may be recommended to test the chemical purity of any given sample of carbon tetrachloride.

Add a drop of metallic mercury to 10 c.c. of the given sample. If the sample is pure, there should be no change of colour. With an impure sample, on the other hand the mercury becomes black, owing to the formation of sulphide of mercury. Since the sulphur impurities seem to be responsible for the toxic effects, the above test is quite sufficient for all practical purposes.—Yours, etc.,

14th December, 1929.

THE STERILISATION OF HYPODERMIC SYRINGES.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the correspondence in your columns on this subject, I am of opinion that the quickest and best method of sterilisation is to simply draw 90 per cent. spiritus rectificatus in and out of the syringe about half a dozen times. I do not carry tincture of iodine with me, but simply paint the part to be injected with spiritus rectificatus from the same phial. I have given thousands of hypodermic, intramuscular, and intravenous injections by this method during the past nine years' practice, and have never seen any sepsis result.

I may add, however, that when giving injections of neosalvarsan, sulfarsenol, diphtheria antiserum or other serum, I am always very particular to wash out all traces of spirit by drawing boiling water in and out of the syringe, as if any trace of alcohol is present, the fluid becomes milky or turbid.—Yours, etc.,

18th December, 1929.

THE PURITY OF TUBE WELL WATERS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I was very interested to see the article by my old friend and brother-officer Lieut.-Col. G. G. Jolly, who is now Director of Public Health in Burma, in your last issue. His article gives an interesting account of a very common occurrence in connection with deep wells. He observes that under certain climatic conditions there is a decided falling off in purity of the water drawn from the tube even though this penetrates the earth for a considerable depth. It is, of course, usually assumed that at a great depth in the earth's surface no bacteria can live, and, therefore, water drawn from this point should show no trace of surface pollution. The assumption is perfectly correct, the water should be sterile. In actual practice it frequently is not. The correct explanation of the occurrence is to be found in one very simple fact, viz., that there is nearly always a small leakage of contaminated subsoil water down the outside of the tube, which ultimately finds its way into the pure deep water around the end of the pipe. An extremely interesting account of this occurrence was reported by Dr. Andrew Balfour, some time in 1908. It was observed that water taken from a very great depth (as far as I remember about 800 feet) was habitually polluted, and also the same organisms that appeared in the supply could be found in the Nile itself. It was suggested that possibly there was some underground fault that communicated between these two sources. Other instances of this have been reported from time to time. In practically every case the same remedy produces a cure of the conditions. If the tube of the well is grouted around the outside with liquid cement forced in

with compressed air, the purity of the water is invariably restored. An explanation is extremely simple; the grouting forms an impervious collar round the tube and cuts off all surface water entirely, and, consequently, removes all chances of pollution. It is significant that in Lieut.-Col. Jolly's article there is a correlation between rainfall and the amount of contamination. This is exactly what one would expect. The nearer the surface the subsoil water is, the greater chance of its being polluted. A few drops of polluted surface water would account for the presence of bacteria at great depths. If Lieut.-Col. Jolly will consult a sympathetic engineer and arrange with him to dig away the earth from the tube for about 8 to 10 feet in the ground, then to grout the tube with liquid cement, hammering it well in with compressed air, he will find that all his troubles will disappear.—Yours, etc.,

W. W. CLEMESHA,
LIEUT.-COL., I.M.S. (retd.).

MALARIA CONTROL SCHEME,
DAYTONA, KANDY, CEYLON,
13th December, 1929.

LEECHES IN CARDIAC DISEASE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—At one time venesection and the use of leeches were recognized as being of value for various ailments, and they are still recommended in cases of urgent symptoms of heart failure with engorgement of the right side of the heart and liver. Whilst abstraction of a small volume of blood (about 8 oz.) followed by the administration of cardiac tonics may not be of permanent value, yet it may alleviate the distressing symptoms for some days, and enable the patient to transact legal and important business. The following are particulars of such a case:—

I was called to see a young married woman, aged 25, who was in a state of acute cardiac dyspnoea. She was unable to speak, or to swallow any nutrition, and had to be propped up on pillows. There was a history of chronic rheumatism, and examination showed a severe condition of mitral regurgitation present. The cardiac dullness extended considerably over on the right side of the chest, whilst the liver was enlarged to three finger-breadths below the costal margin.

I gave an injection of digitalin at once, with gr. v. of calomel, and a stimulant mixture; 15 leeches were applied over the hepatic area.

Next morning the patient had passed a restful night and was much better. Again 15 leeches were applied. For six days the prognosis was almost hopeful, the patient slept well, took ample nourishment, and even—against orders—attempted to walk to the window. There was no dyspnoea, and the liver dullness had diminished. The relief however was only temporary, for on the eighth day the dyspnoea and other symptoms recurred with severity, and despite the further application of leeches and other measures, the patient died on the ninth day.

The abstraction of blood, however, gave an interval of a few days during which the patient was mentally and physically much relieved. A similar case is reported in Burney Yeo's *Manual of Medical Treatment*.—Yours, etc.,

RAOPURA, LIMDAPOLE,
BARODA,
3rd December, 1929.

BLUNDERBUSS THERAPY.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Is a medical man justified in employing Rheumatism Phylacogen, Sulfarsenol, and Plasmoquine injections in a typical case of typhoid fever?

A patient suffering from typical typhoid fever, until the end of the first week, was making satisfactory progress in the hands of a competent and well qualified medical practitioner, when a relative, without consulting the medical attendant, called in another doctor. The

second doctor refused to allow the first to have anything further to do with the case, refused to see him in consultation, and took the case out of his hands. The "remedies" administered were as above. Finally, I was called in, and found the patient almost in *extremis*; there was low muttering delirium, a quick thready pulse, hurried respiration, bleeding from the right ear, incontinence of urine and faeces, and a large and severe bed sore over the sacrum.

The Civil Surgeon was now called in and confirmed the diagnosis of typhoid fever, which was further confirmed by a strongly positive Widal reaction. Fortunately, the patient recovered with proper medical attendance and nursing.

There was never at any time in the case any suspicion of any disease other than typical typhoid fever, and no evidence of rheumatic fever, syphilis, general septic fever, or pernicious malaria. The case is of interest, however, from the unprofessional point of view.—Yours, etc.,

P. S. SARMA, M.D.

SITARAM MILLS, LTD.,
PUSHPAGIRI, TRICHUR, S. INDIA,
25th November, 1929.

THE ALL-INDIA MEDICAL LICENTIATES' ASSOCIATION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—May I crave the hospitality of your columns to draw attention to the Silchar Branch of the All-India Medical Licentiates' Association? The objects of the Association are to create unity with a view to enlisting sympathy for our cause, to review our present position, to devise ways and means for promoting professional progress, scientific knowledge, and welfare; in brief to advance the moral, material, social and intellectual progress of medical Licentiates in this Province, whether they are in government, district or local board, railway, tea garden, or State employment, or engaged in private practice.

Col. G. Hutcheson, I.M.S., Inspector-General of Civil Hospitals, Assam, in his presidential speech at the first provincial conference in 1928, spoke as follows:—"I hope this may be the forerunner of a very successful and prosperous future for your Association, and I would appeal to all Licentiates in the Province to enlist themselves as members as soon as possible. So far, out of about 350 Licentiates, only 178 have responded to the call. I hope your Secretary will soon be able to report that all Licentiates have joined."

Mr. E. S. Roffey, M.L.C., Secretary, Assam Branch of the Indian Tea Association, in his presidential speech at the second provincial conference in 1929, held at Dibrugarh, spoke as follows:—"This, I think, proves that, as your chairman states, you have not been shouting as loudly as you should do. But, before you shout any louder, I should advise you to enrol the whole, or the greater majority, of the Licentiates in Assam as members of your Association. From the proceedings of your conference of last year, I have learnt that the Association was started 23 years ago, that no life in it was shown until 1924, and that last year, out of a total of 350 Licentiates in the Province, only 178, or about 50 per cent. were members of the Assam Branch. I sincerely trust for the sake of all of you that the membership has still further increased, as it is only by combination of the great majority of members of a profession, or industry, or community, that any good results can be attained by the officers of any association. Your officers cannot possibly have the same weight when representing the minority of your profession, as they would have in if they represented the majority."

I would appeal to those Licentiates in the Province who have not yet done so to join the Association, and support us in the programme outlined.—Yours, etc.,

SARAT CHANDRA CHAKRABORTY,
Secretary, Silchar Branch.

8th November, 1929.

Service Notes.

APPOINTMENTS AND TRANSFERS.

THE services of Lieutenant-Colonel W. M. Houston, M.B., I.M.S., are placed at the disposal of the Government of India, with effect from the 2nd August, 1929, and the unexpired portion of the leave granted to him in Government Notification, General Department, No. S. 20/10, dated the 26th February, 1929, is cancelled.

On relief by Lieutenant-Colonel I. D. Jones, I.M.S., on 13th November, 1929, Lieutenant-Colonel A. G. Tresidder, C.I.E., M.D. (Lond.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S., to officiate as Civil Surgeon, Nasik.

On return from leave Lieutenant-Colonel S. S. Vazifdar, M.R.C.P. (Lond.), I.M.S., to be Professor of Medicine and Clinical Medicine and Therapeutics, Grant Medical College and Physician and Superintendent, J. J. Hospital, Bombay.

On relief by Lieutenant-Colonel M. J. Holgate, I.M.S., Lieutenant-Colonel D. D. Kamat, B.A., I.M. & S. (Bom.), L.R.C.P. & S. (Edin.), I.M.S., to be Civil Surgeon, Surat.

On return from leave on 2nd November, 1929, Lieutenant-Colonel A. N. Thomas, D.S.O., M.B., B.S. (Lond.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S., to be Presidency Surgeon, Bombay, with attached duties.

On relief by Lieutenant-Colonel D. D. Kamat, I.M.S., Lieutenant-Colonel S. J. Bhathena, L.R.C.P. & S. (Edin.), L.F.P.S. (Glas.), I.M.S., to officiate as Civil Surgeon, Thana, *vice* Mr. C. T. Dhruv, B.M.S., reverting.

On relief by Lieutenant-Colonel A. G. Tresidder, C.I.E., I.M.S., Lieutenant-Colonel K. G. Gharpurey, B.A. (Cal.), L.R.C.P. & S. (Edin.), L.F.P. & S. (Glas.), I.M.S., to be Civil Surgeon, Ahmednagar.

Lieutenant-Colonel R. S. Townsend, I.M.S., Civil Surgeon, is transferred from Mussoorie to Gorakhpur.

On return from leave on 1st November, 1929, Lieutenant-Colonel M. J. Holgate, O.B.E., M.B., B.S. (Lond.), I.M.S., to officiate as Civil Surgeon, Sholapur, until such time as Major R. H. Candy, M.B., B.S. (Lond.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S., goes on leave when he will officiate as Civil Surgeon and Superintendent, Medical School and Mental Hospital, Ahmedabad.

On relief by Lieutenant-Colonel E. S. Phipson, D.S.O., M.D. (Lond.), M.R.C.P. (Lond.), D.P.H. (Lond.), D.T.M. & H. (Lond.), I.M.S., Major A. C. L. O'Shea Bilderbeck, M.B., B.S. (Lond.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), D.P.H. (Camb.), D.T.M. & H. (Lond.), I.M.S., to officiate as Port Health Officer, Bombay, *vice* Major P. H. S. Smith, M.B., I.M.S.

On relief by Lieutenant-Colonel A. N. Thomas, I.M.S., Major C. M. Plumptre, M.R.C.S. (Eng.), L.R.C.P. (Lond.), F.R.C.S.E., I.M.S., to officiate as Civil Surgeon and Superintendent, Medical School and Mental Hospital, Hyderabad, pending further orders, *vice* Lieutenant-Colonel M. S. Irani, F.R.C.S.E., L.F.P. & S. (Glas.), I.M.S., reverting to Matheran.

On return from leave Major B. H. Singh, M.C., I.M.S., was appointed to be a Resident Medical Officer (Physician) in the Medical College Hospitals, Calcutta, with effect from the forenoon of the 15th November, 1929.

Major A. S. Fry, I.M.S., was appointed to act as First Resident Surgeon, Presidency General Hospital, Calcutta, *vice* Major S. A. McSwiney, I.M.S., transferred.

Major S. A. McSwiney, M.B., F.R.C.S.I., I.M.S., is appointed to act as Civil Surgeon of Bakarganj, with effect from the afternoon of the 8th August, 1929, *vice* Lieutenant-Colonel K. S. Thakur, I.M.S., granted leave.

Major T. S. Shastri, I.M.S., on return from leave, to act as District Medical Officer, North Arcot, and Superintendent, Government Headquarter Hospital, Vellore.

Major H. K. Rowntree, M.C., M.B., I.M.S., Civil Surgeon, Simla East, is appointed to hold charge of the duties of Health Officer, Simla, in addition to his other duties, until further orders.

On return from leave on 3rd November, 1929, Major A. H. Harty, M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S., to

officiate as Resident Medical Officer, St. George's Hospital, Bombay.

On return from leave on 29th November, 1929, Major W. C. Spackman, M.B., B.S. (Lond.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), L.T.M. (Lond.), I.M.S., to officiate as Civil Surgeon, Belgaum, pending further orders.

On relief Major B. Z. Shah, M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S., to officiate as Superintendent of Mahableshwar.

The services of Major H. S. Anand, M.B., Ch.B., D.P.H., I.M.S., Health Officer, Simla, are placed temporarily at the disposal of the Government of the Punjab, until further orders.

The services of Major A. Y. Dabholkar, M.C., M.B., I.M.S., are placed temporarily at the disposal of the Government of Bombay for employment in the Public Health Department, with effect from the date on which he assumes charge of his duties.

LEAVE.

In modification of Government Notification, General Department, No. S.20/10, dated the 28th September, 1929, Brevet-Colonel F. P. Mackie, O.B.E., K.H.S., I.M.S., has been granted, with effect from 8th November, 1929, leave on average pay for 3 months and 29 days, combined with such leave on half average pay as will bring the total of the period of leave to one year.

Lieutenant-Colonel K. S. Thakur, I.M.S., Civil Surgeon, Bakarganj, is granted combined leave for 12 months, with effect from the 9th August, 1929.

Lieutenant-Colonel C. H. Barber, D.S.O., I.M.S., Civil Surgeon, Naini Tal, is granted combined leave for 12 months, with effect from 20th November, 1929.

Major S. N. Mukherji, I.M.S., Superintendent, Campbell Medical School and Hospital, is allowed leave for one year, with effect from the 15th December, 1929, or any subsequent date on which he may avail himself of the leave.

PROMOTIONS.

Captain to be Major.

J. H. Barrett. Dated 2nd November, 1929.

NOTES.

THE ROYAL BATHS, HARROGATE.

We have received from the General Manager, Harrogate Corporation, a very attractive and interesting booklet on the subject of these world-famed baths. There is no need for the invalid from India to go to continental spas. For Harrogate caters especially for cases of intestinal disorder, hepatitis, rheumatism in its many forms, the after effects of malaria, and tropical neurasthenia. In an introductory note Sir Arbuthnot Lane comments on the dangers of dosing patients with constipation with irritant purgatives and speaks very highly of the sulphur waters of Harrogate.

There is no special season at Harrogate, whilst its eighty-eight medicinal springs are all natural and are constant in flow. The sheet anchor of the Harrogate "cure" is the sulphur water treatment, but there is also available every mode of treatment given at continental spas. Harrogate is famous indeed for the variety and quality of the medicinal waters there, for the class of attendants giving the treatments, and for its pleasant and bright climate. The staff at the Royal Baths number nearly two hundred, and, unlike those of other spas are not simply persons engaged for the season, but have all received a full nursing and medicinal training. The cost of the different cures is considerably lower than is popularly supposed to be the case in connection with spas; thus the sulphur baths only cost 12s. a week, and the more elaborate treatments 25s. a week. Accommodation in the town at private hotels, boarding houses, etc., can be obtained at from 3½ guineas a week upwards.

In addition to its medicinal springs, Harrogate has a splendid and bracing climate, whilst the pleasure seeker,

the golf and tennis enthusiast, are specially catered for. It is also a motoring centre within easy reach of many interesting places, whilst excellent schools and educational facilities are available.

A second interesting booklet deals with the medical aspects of the Harrogate cure. The many medicinal springs of Harrogate owe their existence to a vast store of soluble minerals of varied nature at great depths below the surface,—sufficiently deep to result in a fairly constant temperature in the springs throughout the year. The saline sulphur baths are used chiefly in the treatment of gout, rheumatism, hepatic disorders, and skin diseases; the alkaline sulphur baths are used in such skin disorders as eczema, psoriasis, acne, lichen planus, etc., whilst constant, interrupted, and sinusoidal currents are available for treatment of muscular and neuritic types of disorder. Carbonic acid, "Nauheim" baths are used for heart diseases and rheumatism. Other treatments used are massage douches, the Plombières treatment, peat baths, local steam baths—the Berthollet treatment, diathermy, Bergonie treatment, wax baths for dealing with stiff and painful extremities, and Turkish baths.

Those of our readers who are contemplating sending patients Home for spa treatment will do well to write for a copy of both brochures.

THE SQUIBB BUILDING.

MESSRS. E. R. SQUIBB & SONS, are one of the largest and best known American chemical manufacturing firms, and their dental cream, milk of magnesia, and other products are well known. The firm has recently decided to move into new quarters in the Plaza section of Fifth Avenue in New York. The new building is a typical skyscraper of 32 stories, of which E. R. Squibb & Sons will occupy 12, the rental being a sum of \$7,000,000 for a period of twenty-one years. The new building is to be named the "Squibb Building" in honour of its chief tenants.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers, relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India, Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

CHOLERA IN A KHASI VILLAGE AND ITS TREATMENT WITH BACTERIOPHAGE.

By J. MORISON,

LIEUTENANT-COLONEL, I.M.S.,

Director, King Edward VII Memorial Pasteur Institute
and Medical Research Institute, Shillong,

B. K. PAL CHOUDHURY, B.SC., M.B. (Cal.),

and

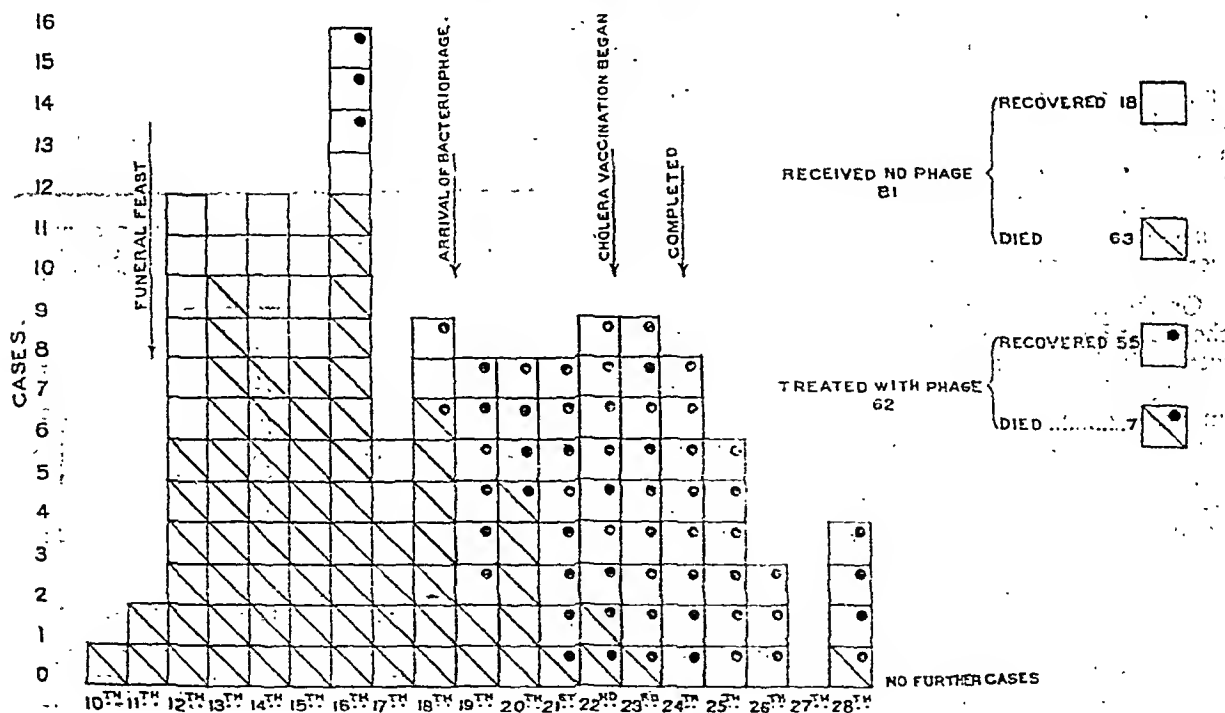

SUB-ASSISTANT SURGEON M.D. H. RAHMAN.

JAKREM is a village in the Khasi Hills 16 miles by road and twenty-five by footpath south-west of Shillong. It consists of 142 houses and has a population of 744. Never in the memory of the villagers has it been visited by cholera. On the 3rd October, 1929, eleven men went to seek work two days' march south to Maodon, adjacent to the plain of Sylhet. On their arrival they found cholera in Maodon and two neighbouring villages and, after staying one night, they returned

together with one man from Sngimowlein. About two miles from Jakrem this man left the party, his path diverging, and very soon after his arrival home he died of cholera; there were four more deaths from cholera in Sngimowlein. The Jakrem party, however, were met by the village elders and were forbidden to enter Jakrem. They remained where they were for two days while an egg-breaking ceremony was held at Jakrem to determine whether the cholera demon (*ka khilam*) was with the party. The cholera demon has six hands but no legs. According to the Khasis "*ka khilam* resides in the plains and can only leave the plains and climb the hills to Jakrem on the shoulders of a Khasi." The break of the egg showed that the demon was not with the party and they were then allowed to resume their journey to Jakrem. On the way they were met by one Saboo of Jakrem, who had a paddy field and a shelter near by, and in his field they all fed together and ate food which had been prepared at Maodon. They all reached Jakrem that evening (10th October).

That night Saboo was seized with vomiting and purging and the following day he died. Relying on the egg ceremony, it was held that Saboo could not have died of cholera and his body, instead of being buried as is done when one dies of cholera, was given a ceremonial cremation. Saboo was a man of importance so the cremation was followed by a big feast. Late that night Saboo's son and a neighbour fell ill

CHOLERA IN JAKREM VILLAGE.

and both died on the 11th. On the 12th there were 12 cases and the epidemic which comprises 143 cases with 70 deaths continued till the 28th (see Graph). Two of the party who had gone to Maodon took ill, the one on the 15th and the other on the 16th. Both died on the 17th. There were no cases of dysentery.

On the 12th it was realised that the disease was cholera. Panic seized the village, and all who were able fled to the surrounding fields and woods leaving behind them the sick, the dying, and the unburied dead.

The village teacher and the family of the late *siem* (chief) are Christians; they did not attend the feast, they remained in the village and none of them got cholera. A neighbouring hamlet, "Smithnah," about one mile from Saboo's house, took no part in the feast and not one of the 44 inhabitants have had cholera. Saboo's house is in the western section of Jakrem. This section is separated from the eastern by a small valley. From the western section every house was well represented at the feast, while from the eastern section only one or two came from each house and many houses sent none. During the first five days of the epidemic there were 29 cases from the west section and 9 cases from the east.

Incidence of Cholera in the Houses.

Western Sec., Houses 1—83.
October 1929.

Eastern Sec., Houses 84—142.
October 1929.

A few people from Nongpenden, two miles away, joined the feast and two of them died of cholera six days later.

For the feast two cows and many pigs were killed. The feast consisted of cooked meat, potatoes, rice and rice beer (*ka kiad*). No milk or milk foods were taken.

There is no common water supply for the village. Water is drawn from small springs, three or four houses using water from the same spring. It was noted that unaffected houses and infected houses in several instances used the same spring. Flies were notably absent.

Saboo's wife attended her husband during his illness and took a leading part in the preparation of the feast. She herself did not get cholera. Women and children suffered heavily; among 70 deaths there were 20 men, 35 women, and 15 children under twelve years of age.

All the food for the feast was cooked, hence infection must have taken place during the distribution. The food at the feast was, and is normally in a household, distributed in small brass dishes. Larger pots were used for the cooking. Dr. Choudhury and Dr. Rahman twelve days later each happened to see these same dishes being used to remove the excreta from helpless patients and, on enquiry found that this frequently occurred and that the dish after scouring with sand and water was returned to its ordinary use. Saboo's wife could not remember having used such dishes for this purpose but apparently was not sure whether this had occurred.

Information of this outbreak reached the Rev. J. J. M. Nichols Roy at Shillong on the 16th October and the messengers were at once sent to the Pasteur Institute. On the morning of the 17th these men, taking with them a supply of cholera-dysentery bacteriophage, left for Jakrem, arriving there late that evening. Within three days nineteen patients had received bacteriophage. One of these died, but the rest recovered. By midday on the 22nd Dr. Pal Choudhury from the Pasteur Institute and Sub-Assistant Surgeon Md. Rahman of the Gauhati epidemic unit arrived, and all the survivors on that day and all taking ill subsequently received the bacteriophage. The villagers took courage and began to return, and that evening, after the more desperate cases were attended to and the burial of the dead was arranged, cholera vaccination was begun. By the 24th most of the villagers had been inoculated.

If we divide the epidemic into those taking ill between the 10th and the 17th October, when no bacteriophage was available, and those falling sick between the 18th and the 28th when the bacteriophage was at hand, we have:—

	Cases.	Deaths.	Mortality.
Group I	71	51	71.8
Group II	72	19	26.4

Or taking the cases receiving and not receiving bacteriophage:—

	Cases.	Deaths.	Mortality
Without bacteriophage ..	78	63	80.8
Receiving bacteriophage	65	7	10.8

Or taking cases falling ill on and after the 18th when bacteriophage was available:—

	Cases.	Deaths.
Not receiving bacteriophage ..	13	12
Receiving bacteriophage ..	59	7

According to Dr. Choudhury, who saw 54 cases, the cases were not dissimilar in initial severity to those he has seen elsewhere in Assam; but, be that as it may, the graph shows a sudden change in the character of the epidemic which at once followed the distribution of the bacteriophage on the 18th October. Six hundred and sixty persons were inoculated with cholera vaccine between the evening of the 22nd and that of the 24th. It is difficult to appraise the action of the cholera vaccine as the epidemic had already changed its character before vaccination began, and ceased on the fourth day after it had been completed.

The treatment with bacteriophage was simple. All food was withheld for the first day. As much water as the patient could sip or drink was given and with the water 2 ml. of bacteriophage of the combined cholera-dysentery strains were administered every 2 to 4 hours until the vomiting and purging ceased and urination began.

Five cases were given intravenous saline as well as bacteriophage and of these two died. More cases would have received this had it been possible to give it in the stress of the work. No other drug was used.

Discussion.—The epidemic occurred in virgin soil. From the start to the 9th day the mortality was maintained at a high level; on the 9th day 7 out of 9 cases taking ill died. With the introduction of the bacteriophage there was at once a change. A similar change happened in a smaller epidemic in Shillong, where of 21 cases receiving no bacteriophage 16 died, and of 6 cases that had bacteriophage 1 died.

d'Herelle believes that cholera epidemics are brought to an end by the development of bacteriophage in those who recover and its distribution by the agencies that distribute infection. To the development of the bacteriophage also he attributes the diminution in the mortality frequently observed towards the end of an epidemic. If this be true, then the administration of an active bacteriophage may have precipitated a development that, occurring more slowly, is normal to the disease. A sudden change in the character of the disease such as took place at Shillong and again at Jakrem is not a feature of cholera untreated or treated in the ordinary way.

The results at Jakrem were obtained under severe conditions. No nursing was possible. One of the deaths in the bacteriophage group was a man who, feeling hungry, got up and attempted to cook some food. He collapsed and died by the fireside, when, had he had some one to help him, he seemed on the fair way to recovery.

NOTES ON THE PATHOGENESIS OF SPRUE AND THE ASTHENIC DIARRHOEA OF INDIANS.

WITH SPECIAL REFERENCE TO THE RÔLE PLAYED THEREIN BY AMOEBIASIS. THE PROBABLE IDENTITY OF THE TWO FORMER CONDITIONS, AND THEIR CONNECTION WITH ADDISONIAN ANÆMIA—SUBACUTE COMBINED DEGENERATION OF THE CORD—HUNTERIAN GLOSSITIS SYNDROME OF HURST.*

By J. B. HANCE, O.B.E., M.A., M.D. (Cantab.), F.R.C.S.E.,
MAJOR, I.M.S.,

Rajkot.

It is not without considerable trepidation that I put forward this paper for discussion before an audience which includes many clinicians and laboratory workers whose experience far exceeds my own. It concerns a subject which you, Sir, and your colleagues in Calcutta, have made peculiarly your own, and I hasten, therefore, to emphasize that these remarks are put forward in no spirit of dogmatism and express no fixed idea; but rather that they are made with the deliberate purpose of provoking discussion and of enabling me to profit by the views and experience of my audience in a class of case which is daily coming more into prominence and claiming more attention from our profession.

Briefly, the question which I have to bring forward for discussion is whether the time has not arrived to revise our conception of sprue and the so-called pernicious anæmia and asthenic diarrhoea of Indians, as separate clinical, ætiological and pathological entities, and to regard them as members, differing if at all, only in degree, of the syndrome Addison's anæmia, subacute combined degeneration of the spinal cord, and Hunterian glossitis, resulting from a combination of achlorhydria, or achylia gastrica, and intestinal infections by the hæmolytic streptococcus.

The term Addison's anæmia is used in this paper instead of pernicious anæmia. Addison first described what he termed idiopathic anæmia in 1847. Twenty years later Biermer wrote also upon the same subject, calling it pernicious anæmia; but, as Hurst has pointed out, "beyond the pernicious name he invented, he has added little to our knowledge of the subject."

While an infective basis for Addisonian anæmia had long been suspected, and in the case of subacute combined degeneration had been foreshadowed as far back as 1900 by Risien Russell. Batten and Collier (1900), it was not until the early years of the present decade that Hurst and his colleagues established that both these diseases are causally associated with intestinal infection with a hæmolytic streptococcus in the presence

of complete achlorhydria. The latter may be primary and constitutional, or secondary, following upon such conditions as alcoholic or toxic gastritis or carcinoma of the stomach.

These workers regard the hydrochloric acid in the gastric juice as an "antiseptic barrier" (Knott), the lack of which permits streptococci from the teeth, tonsils or nasal sinuses to gain access to the duodenum where they find in the alkaline products of proteolysis a favourable culture medium.

With regard to Hunterian glossitis, Hurst (1925) states that this was described by William Hunter as a sign of Addisonian anæmia; but the description fits equally the tongue conditions observed in sprue, asthenic diarrhoea and subacute combined degeneration. Its main characteristic is its smooth polished appearance due to the denudation of the filiform papillæ. It is seen at its extreme in the classical case of sprue and may be observed in all its phases in any of the conditions under consideration. It has frequently drawn my attention to a possible infection with the hæmolytic streptococcus which subsequent search has usually confirmed. For the sake of brevity, therefore, I shall henceforward refer to this syndrome of Addison's anæmia, subacute combined degeneration of the spinal cord, and Hunterian glossitis, as Hurst's syndrome.

With this advance in our knowledge of pathogenesis, we are justified in reviewing our data with regard to sprue and its associated conditions. The sprue-like diarrhoea of Addison's anæmia has long been recognized, and the Addisonian type of anæmia in sprue is equally well known. The latter is stressed by Acton and Knowles (1928), while the former is foreshadowed by Hurst (1922), who states that beyond Addison's anæmia, the only conditions in which a hæmolytic anæmia associated with megalocytosis which is typical of that disease occurs, are sprue and Bothriocephalus infection.

In Kathiawar asthenic and sprue-like diarrhoea appear to be so prevalent as almost to deserve the description endemic, and the foregoing considerations have prompted an analysis of the records of 26 consecutive cases for the purposes of this paper. So prevalent and well known is this condition that it is known in Gujarati as *Bombay-no pani*, from the belief that the causal agent is the water of Bombay! Whatever may have been the case in the past, it would seem to be an undeserved slur on the Bombay of the present, with its carefully protected water supply, since only two of the present series of cases developed the disease in that city. In all the remainder, the disease appears to have been contracted in Kathiawar.

I must at once admit that I have been unable to find any distinction, except in degree, between cases in this series which would be returned as typical sprue, and others which would be characterized as asthenic diarrhoea. In others again the anæmia has dominated the picture, and in

*A paper read before the Medical and Veterinary Section of the Indian Science Congress at Allahabad on 3rd January, 1930.

three the main symptoms have been nervous; but in all the clinical picture has been one of chronic wasting with flatulence and diarrhoea associated with true Addisonian anæmia and Hunterian glossitis. The evidence which has led me to put forward the suggestion that these two conditions are essentially identical in ætiology, pathogenesis, and treatment, and that they are phases of Hurst's syndrome, may be divided, for purpose of consideration, into clinical, pathological and therapeutic; and consideration has led me also to put forward the tentative suggestion that it is usually caused, at any rate in Kathiawar, by the co-existence of intestinal ulceration with the infection of these ulcers by a hæmolytic streptococcus. Further, whereas Acton and Knowles (1928) put forward the view that sprue is a sequel of bacillary dysentery, my evidence leads to the conclusion that, at any rate in the locality for which I speak, *Entamoeba histolytica* is much more often the culpable agent, since in 15 out of the 26 cases, or roughly 60 per cent., cysts of this organism were found; whereas in 15 cases examined for both amebic and by agglutination for bacillary dysentery, only two cases (12.3 per cent.) showed a positive agglutination, to *B. dysenteriae*, and in both cases the organism agglutinated was *B. flexneri*. Of the same 15 cases, 10 (or 66 per cent.) showed *E. histolytica* cysts. One case both harboured cysts and agglutinated the bacillus of Flexner.

This appears to me to point to the conclusion, reached by Hurst and his collaborators, that the streptococcus is the true culprit, and what I may term the "ulcerating organism" merely its vehicle, and ætiologically of secondary importance; since when putting forward laboratory evidence I shall show you that in only 3 cases of this series did we fail to isolate this organism. One of these cases is still awaiting a radiological dental survey, so we have not yet lost hope.

Turning now to the clinical aspect, the condition which I am discussing, like those comprising Hurst's syndrome, is a disease of middle age. The average age of the series of patients under review is 36, the oldest being 55 and the youngest 19, and the majority between 25 and 40: 23 were males and 3 females; but I do not place much ætiological significance on these figures, since even in Kathiawar, which is more liberal in this respect than Northern India, far fewer women than men consult a male doctor. Sprue, by some authorities, is considered to be a disease of the European resident in the tropics. My series contains only one European, but several patients presented typical clinical pictures of sprue. Hindus were twice as often affected as Mohamedans, this being approximately proportional to the class incidence of the population; but it has further the significance of vegetarians being twice as often affected as non-vegetarians. Sixteen were Hindus, 8 Mohamedans, 1 European and 1 an Indian Christian.

Addison, who described what he called idiopathic anæmia in 1847, wrote that it "occurs

chiefly in persons of a somewhat large and bulky frame and with a strongly marked tendency to the disposition of fat." More recently Hurst and Draper have amplified this description by noting that these patients approach the hyperpituitary type in appearance, having a wide facies, eyes set far apart, broad jaws and a wide costal angle. In the present series of cases I find the latter characteristics faithfully observed, as will be evident from the accompanying photograph but, owing presumably to the asthenic condition of the majority of the cases, bulkiness of frame cannot be called a characteristic, except in those members whose most prominent symptoms were referable to the nervous system.

The characteristic history is one of an antecedent digestive disturbance, which may have been frankly dysenteric, as in 11 cases of the present series, or merely looseness as in 9 others. This is followed by a continuance of digestive troubles, which in some consists in the passing of large pale "porridgey" or frothy stools in the morning, in others of a constant and irritating looseness throughout the day. The first of these categories may, and frequently does, progress into the second, and both may alternate with periods of constipation. In only two cases of the series was constipation noted as the prominent digestive symptom.

As the condition progresses soreness of the mouth and tongue is added to the picture, and this presents every degree of severity, from inconvenience in consuming hot or spicy food to a rawness which makes a purgatory of the taking of any food at all. Soreness may not be confined to the tongue but ulceration and rawness of the cheeks and lips may add to the patient's trials, and gives to the condition the expressive vernacular name of *munh*. As the disease progresses further, fatigue on exertion, breathlessness and

increasing pallor with a host of other symptoms supervene. Among the more characteristic of the later are irregular low fever, indigestion and flatulence, sternal pain, cedema of the feet and burning or tingling of the extremities, which may be followed, if the case is far advanced, by a definite ataxia.

On examination, besides the structural characteristics already noted we see an emaciated patient with the *facies Hippocratica*, of marked, often extreme, pallor, who may be a living skeleton, or again whose podgy bloated abdomen—sometimes revealing the peristalsis of the bowels beneath—may form a striking contrast to the emaciation of the rest of his frame. The pallor is extremely noteworthy and is of the typical lemon hue. In darker skinned persons difficulty is, of course, experienced in this respect, the complexion tending to assume a muddy chrome colour; but examination of the oral mucous membrane, and especially of the soft palate is an infallible guide. There the submucous fat takes on the classical yellow which Hurst (1922) states "affords just as good evidence of hæmolysis as the Prussian-blue reaction obtained in the liver and sometimes in other organs after death."

The teeth show the usual tartar and pyorrhœa of the Indian adult—and in some cases are very foul. On the other hand they may be surprisingly good. In 6 of the present series they are recorded as foul, in 3 fair, and in 7 good. The remainder are not noted upon. Speaking generally, and with the remark that I often differ materially from members of my staff in my estimation of dental condition, the teeth are poor and mostly infected.

The abdomen may in the earlier cases appear normal, but usually, as I have mentioned it is either distended, with or without visible subjacent peristalsis, or retracted. The liver and spleen are seldom notably enlarged, but there is often tenderness on deep pressure upwards into the right hypochondrium. An almost invariable sign is tenderness over, and thickening of the colon in one or other, or both, iliac fossæ, indicative of colitis; and in some cases the whole of the large intestine as far as the iliac colon is so thickened and tender that its location is evident on palpation.

The respiratory system is not usually conspicuously affected; but here a note of warning must be sounded. Two cases in the present series gave a history of cough with evening pyrexia which led to their admission as cases of suspected phthisis—a diagnosis which was only abandoned after repeated negative clinical, sputum and x-ray examinations, and upon the establishment of definite positive evidence of Hurst's syndrome. These cases showed a generalized bronchitis on examination. Similar instances have come into my experience in cases seen in consultation with other medical men, and of which unfortunately no record has been preserved; and there is undoubtedly danger of overlooking early cases of Hurst's syndrome if the glasses through which

one views them are too coloured by the prevalence of pulmonary tuberculosis.

Other respiratory symptoms which are not infrequent are dyspnoea on exertion—a sequel of the profound anæmia—and asthmatic attacks which, I conclude, are an expression of a streptococcal focus.

The most constant cardio-vascular symptoms are palpitation on exertion and sternal pain; and of physical signs the most notable is the so-called hæmic murmur. The heart sounds, especially the first, are also often poor in quality. The pulse is rapid, expressive of an attempt to maintain oxygenation with diminished hæmoglobin, and may be small and thready; occasionally it is intermittent.

The blood picture is the most striking feature of the case on examination. It is typical of the Addisonian or so-called pernicious anæmia; red cells greatly diminished, hæmoglobin also greatly reduced, but usually not proportionately, giving a colour index usually greater than unity. This, however, is by no means necessarily the case. Hurst (1922), Musser (1926) and others have noted this; and it is the experience of all clinicians that "Addison's anæmia, particularly in its early stages, and during the periods of remission, may present a blood picture far removed from what is considered to be typical of the disease." This is well illustrated in two of the present series, on whom repeated blood counts were carried out (Table I). The diagnosis must rest not upon the colour index, but upon the nature of the red cells observed. Poikilocytosis and anisocytosis are common. Megalocytes are invariable; and upon their presence alone a diagnosis of Addisonian anæmia may be reached. Normoblasts and megaloblasts may be observed. The former were not seen in the present series, the latter once.

There is also usually a more or less marked leukopenia, but the differential leucocyte count does not vary greatly from the normal.

The serum when separated has a characteristic yellowish tinge analogous to that observed in the subcutaneous fat.

Signs and symptoms referable to the nervous system may, or may not, exist according to the degree to which the disease has progressed. Five cases in the present series (20 per cent.) showed the paræsthesia of the extremities characteristic of early subacute combined degeneration of the cord, while two others were admitted with the second or ataxic phase of that disease well established.

As regards the urino-genital system there may be slight albuminuria; but casts are seldom seen, and when present are indicative of associated renal disease. Diminished menstrual flow or amenorrhœa is the rule in women.

Coming now to laboratory evidence, I must beg your indulgence, Sir, and that of my audience, if I deal more in actual figures than has heretofore been the case. The investigations, other than routine clinical and blood examination, which

have been performed are:—blood culture, stool examination and culture, examination of the gastric juice for free hydrochloric acid, urine culture and, occasionally, culture from the root of extracted teeth; and the point which I wish at once to make is that in 23 out of the 26 cases, or practically 88.5 per cent., a hæmolytic streptococcus was isolated on culture from either blood, stools, or teeth.

Of these 23 positive cultures 6 were from the blood, and 17 from the stools, while 2 cases showed this organism in both blood and stools, and one in blood, stools and teeth.

Coming now to the "ulcerative organism" or vehicle of the streptococcus, in all the cases stool examination and culture was performed. In 15 (60 per cent.) *E. histolytica* cysts were found and in 1 case, nearly 4 per cent., the bacillus of Flexner was isolated. In 15 of these cases the agglutination test for dysentery bacilli was also performed and was found positive to the bacillus of Flexner in 2 cases, one of which also harboured *E. histolytica* cysts. Thus *E. histolytica* was the presumptive culprit in 14 out of 25 cases or 56 per cent., the bacillus of Flexner in 2 out of 25 cases, or 8 per cent., and both in 1 out of 26, or nearly 4 per cent. In the remaining 32 per cent. organisms of neither disease were found and reliance has to be placed upon history. Twenty-one cases in all, or 80 per cent. either revealed evidence, or gave a history, of dysentery. *Monilia psilosis* was not isolated in any case of the series.

Examination of the gastric contents by Ewald's test meal—fractional test meals unfortunately being impracticable—was performed in 21 cases. In 18 (86 per cent.) there was complete absence of free hydrochloric acid, and in the remaining three (14 per cent.) there was marked deficiency.

Coming now to the therapeutic aspect, the system of treatment which has been followed may be summed up as the combined treatment of chronic dysentery and of Hurst's syndrome. It

has been simultaneously to attack the ulcerating organism and the streptococcus, with appropriate anti-dysenteric treatment combined with autogenous anti-streptococcal vaccine;—emetine and kurchi where the *Entamoeba histolytica* was found, serum and vaccine where the bacillus of Flexner was observed. Coincident with the attack on the organisms, the absent or deficient hydrochloric acid was replaced or supplemented by the administration of the pharmacopœial dilute hydrochloric acid by the mouth, and the stimulation of the hæmatopoietic function by the liver diet of Minot and Murphy, and the exhibition of iron and arsenic. In two very severe cases this has been supplemented by the transfusion of blood from appropriate donors.

My reason for claiming therapeutic evidence in support of my suggestion is that with the exception of one case who was practically moribund on admission, with a count of only 368,000 red cells per c.mm. and a hæmoglobin percentage of 10, and two others who refused to stay in, every case showed immediate and marked subjective improvement, while the objective improvement, though variable in detail in different cases, was no less marked. Of the exceptions, the first case after a considerable subjective, and slight objective, improvement after transfusion died following the first injection of autogenous vaccine. The dose given was only $\frac{1}{2}$ million organisms, but even this was probably too great for his extreme cachexia since he progressively sank thereafter and died 24 hours later in spite of all restorative measures.

In the remainder the improvement was immediate and in some cases dramatic. Soreness of the tongue abates and disappears. Diarrhoea ceases, and formed brown motions replace the pale yellow liquid or bulky grey porridgey stools. Flatulence and dyspepsia cease as if by magic after a few administrations of acid during meals. The weight rises with surprising suddenness. In most cases also there is a dramatic change in the

blood picture, very marked in the earlier phases, less so as the count approximates to the normal; and the more marked the anæmia on admission the more striking is the earlier improvement. In Table II, I give the rosy side of the therapeutic picture—two cases whose improvement was immediate, dramatic and sustained. The side which is not so rosy has already been presented in Table I, showing two cases whose blood picture fluctuated for some time. In one case it did not improve, in the other it settled down later to a steady improvement. In spite of this coyness in the blood picture, other symptoms progressively improved and patients gained in weight and condition and were discharged to continue liver and acid in their homes. It is noteworthy that the first of these cases, whose blood reaction was not satisfactory, was one of the three cases in which we failed to isolate a hæmolytic streptococcus.

and Addison's anæmia. Acton and Knowles (1928) have produced a formidable series of charges against the hæmolytic streptococcus and have considered sprue as a sequel of bacillary dysentery. Discrepancies there admittedly are. Hurst and his colleagues incriminated a long-chained hæmolytic streptococcus from the duodenum. My cases gave a short-chained organism from the blood, stools, or teeth, and I was unable to examine the duodenal contents. Again in only 8 of my cases was the classical sprue stool recorded, the others were cases of colitic diarrhœa. Here, however, I am on common ground with others. Musser (1926) states that Ashford, in an investigation of 616 cases of sprue, found the classical stool in only 19 per cent. In my cases it was shown in 40 per cent. of those whose main symptoms were gastro-intestinal, and in 32 per cent. of the whole series.

Summarizing, I have endeavoured to place before you a series of 26 cases, of which 20 were either sprue or asthenic diarrhœa, 3 were subacute combined degeneration of the cord, and 3 others frank cases of Addison's anæmia, and all of which showed, in greater or lesser degree, evidence of Hurst's syndrome. I have also attempted to show that chronic dysentery—in this series, usually amœbic,—was an established precursor in 68 per cent. of the cases and was a presumptive antecedent in 80 per cent.

Hurst and others have established the guilt of the hæmolytic streptococcus combined with achlorhydria for the conditions comprising their syndrome; and I have tried to place before you to-day evidence which appears to me to throw a strong suspicion on that organism with regard to sprue and asthenic diarrhœa, sharing as they do with frank cases of Hurst's syndrome in symptoms, in organism isolated, and in reaction to treatment.

The idea is not new. Musser (1926) in an admirable paper canvasses the identity of sprue

What, then, is the factor determining the character of the stool in these cases? I can but suggest that as in Addison's anæmia the hæmolytins are predominant in the streptococcal toxins and the neutrotoxins secondary—the reverse being the case in subacute combined degeneration—one must assume that in cases with classical sprue stools these organisms also produce a toxin specially selecting the pancreas for attack. An alternative explanation is one suggested by a case which I was lucky enough to see in Guy's Hospital when last at Home. A case of typical sprue developed acute appendicitis and at the operation the glands at the root of the mesentery were observed to be greatly enlarged. The lacteals in the mesentery of the small intestine were also found to be dilated up to the size of a lead pencil, presumably due to obstruction of their contents by the enlarged glands. The natural result was the failure to absorb the split fats which were passed in the stool. It is possible that long continued enteritis with secondary adenitis may in some cases determine the fatty character of the

stool of sprue. But these discrepancies appear to be only matters of detail, and not seriously to affect the main clinical picture, which seems to me to be most easily appreciated on the assumption which I have suggested, namely, that sprue and asthenic diarrhoea are identical and that both must be added to Hurst's syndrome.

I admit that the evidence is not complete—outside of purely laboratory investigations it seldom is; and this is a clinical series, based on observations which are largely clinical. My excuse and my justification is that it was by clinical observations that those whom Sir Humphry Rolleston has described as "our fathers in physic" arrived at the conclusions on which the science and art of modern medicine are based. From Hippocrates, Galen and Vesalius down to Addison and Bright and to others who are still with us, their clinical observations stand to-day as models of philosophic investigation, to inspire those of us who follow after. The present paper is a stumbling and humble attempt so to follow. No one is more conscious of its many imperfections and of the many gaps left in it than myself, and no one awaits with more eagerness the opinions and experience of others which I hope will be given to me in the ensuing discussion.

URTICARIA DUE TO FILARIAL TOXIN.*

By H. W. ACTON,

LIEUTENANT-COLONEL, I.M.S.,

Director, and Professor of Bacteriology and Pathology,
and

S. SUNDAR RAO, I.M.P.,

Darbhanga Research Scholar,
Calcutta School of Tropical Medicine and Hygiene.

INTRODUCTION.

DURING the course of our researches, the senior author (1925) pointed out the necessity to look carefully for the possibility of filarial infection giving rise to giant urticaria. Though as yet no

relationship has been established between filaria and giant urticaria, one important result of this investigation which lasted over the period 1926 to 1929 was the definite finding of the relationship of urticaria to filarial infection.

During this period, we have observed several characteristic cases of urticaria which could be definitely ascribed to infection by *Filaria bancrofti* and as these cases are very remarkable—evidently the first records of such a manifestation of filarial infection—it may be of interest to discuss them here. Seven of the typical cases that were under observation during this period are discussed below:—

HISTORY OF CASES.

Case 1.—Mrs. C. Anglo-Indian, aged 60, was admitted into the hospital with a history of urticarial eruption appearing all over the body but chiefly on the extremities. The urticaria appeared in crops every day for three months. The patient was then free from urticaria for a period of two months, when she again had a recurrence. Eosinophiles—6 per cent.

Case 2.—Miss S. E., aged 20, had attacks of filarial lymphangitis of the left forearm during 1928, and had a course of vaccine treatment. She was free from these attacks of lymphangitis for a whole year, and was then admitted into the hospital (September, 1929), on account of urticaria of the left forearm. The urticaria appeared once every fortnight with slight febrile disturbance. Eosinophiles—9 per cent.

Case 3.—Miss G. Anglo-Indian, aged 12, was admitted into the hospital in September, 1929, on account of urticaria which was very periodic and appeared regularly every morning some time before food and gradually subsided during the course of the day. The duration of such attacks was two months. Eosinophiles—10 per cent.

Case 4.—C. S. M., Indian Christian, aged 25, male, was admitted into the hospital in August, 1929, with a severe crop of urticarial eruptions all over the body and extremities. He gave a history of slight rise of temperature, which was not recorded, during the course of the eruption. There was no rise of temperature during his stay in the hospital. Microfilariae were present in the peripheral blood. Eosinophiles—5 per cent. This patient was re-admitted into the hospital exactly one month later with a filarial abscess in the right inguinal region which was operated upon and adult filariae were recovered from it. This case has been previously reported in this journal (Acton and Rao, 1929).

Case 5.—B. B. R., Hindu, aged 14, male, was suspected to be suffering from epidemic dropsy and was admitted into the hospital. On examination, it was found that he was not suffering from epidemic dropsy. It was discovered that he had transient urticarial eruption appearing on all the extremities, lasting from 4 to 9 p.m. daily, and subsiding thereafter, and slight puffiness of both the lower extremities towards evening every day. These periodic urticarial attacks continued for over a month after admission into the hospital. These attacks gradually diminished after the commencement of a course of treatment with filarial vaccines and soamin. Microfilariae were present in the peripheral blood taken at night. Eosinophiles—9 per cent.

Case 6.—Miss C. S. F., Anglo-Indian, aged 40, was admitted into the hospital with an attack of filarial lymphangitis of the left leg. During her stay in the hospital she had an attack of urticarial eruption, limited to the left leg and combined with a slight rise of temperature (99.5°F.). In this case no microfilariae were found in the peripheral blood at night. Eosinophiles were 3 per cent.

Case 7.—Mrs. X, Jewess, aged 40, had an attack of urticarial eruption in December, 1929. The attacks appeared once every month and lasted for four days. This case is being further investigated.

* Being a paper read before the Medical and Veterinary Section of the Seventeenth Indian Science Congress. Allahabad, January, 1930.

DISCUSSION OF RESULTS.

In all these cases a thorough routine examination of the blood, stools and urine was carried out to ascertain whether any known specific infection was present to account for the urticaria. Secondly, dermal tests (testing the different food proteins on the skin of the forearm) were carried out in several of these cases and the results were very varying; for instance, in case No. 1 reaction followed most of the food tests. In case No. 4, on the other hand, the tests were entirely negative except for the fowl group. Excluding case No. 1 no definite sensitiveness to particular food proteins was found, and even this case (No. 1) is probably an instance of hypersensitiveness, since she showed marked reaction to almost every one of the tests. Thirdly, all the cases discussed, except Nos. 6 and 7, showed microfilariae in the peripheral blood taken at night. Lastly, all the cases had a moderate degree of eosinophilia.

The presence of microfilariae in the blood is direct evidence of filarial infection. The history of filarial lymphangitis, the concurrence of these attacks with urticaria, the absence of any specific infection, or evidence of any relation of the attack to any particular food indicate that the attacks of urticaria are filarial in origin. This is further borne out by the presence of a moderate eosinophilia (less than 15 per cent.) and the periodicity of the attacks.

It was mentioned before that the attacks of urticaria showed a periodicity in the cases under observation. In cases Nos. 2 and 7, the attacks came on once a fortnight or once a month. This periodicity and the evidence of febrile disturbance together with the previous history of filarial lymphangitis, indicate that the attacks of urticaria are probably mild manifestations of filarial lymphangitis. In case No. 6, after several severe attacks of filarial lymphangitis, the attack became much milder and finally only urticaria occurred which was restricted to the affected limb.

In cases Nos. 3 and 5, there was a daily periodicity of mild urticarial attacks, limited to the limbs; in the former the eruption appeared in the mornings, and in the latter during the evenings. Here, their appearance was without any relationship to food.

Case No. 4 had a single severe attack of urticaria which subsided, and exactly a month later the adult worm was recovered from an abscess. This case has been free from any filarial manifestation since.

So far it has not been established that urticaria is often a definite manifestation of filarial infection. There seems to have been no reference in the previous literature to the correlation of urticaria to filarial infection. In endemic areas, the occurrence of urticaria is a factor to be recognized although the proportion of these cases is small.

It should be admitted that cases of urticaria due to filarial infection are frequently missed.

This happens because it is usually a very transient condition, preceding an attack of filarial lymphangitis, as shown in cases Nos. 2 and 6 discussed above. Another factor masking the location of urticaria in Indian cases is the pigmentation of the skin. Lastly, since urticarial attacks are produced by several other factors, they have been missed in cases where they should have been definitely ascribed to filarial infection. In this connection it may be pointed out that all the cases discussed above (except Nos. 2 and 6) were admitted into the hospital for various causes and not for filarial infection.

Acton (*loc. cit.*) has shown that giant urticaria is usually the result of sensitiveness to certain foods. The various pressor bases act in two ways: (a) on the involuntary muscular fibres, dilating or constricting the capillaries, and (b) increasing or diminishing the cell permeability of the endothelium. In much the same manner, the urticaria produced in the cases discussed here is due to certain foreign proteins liberated by the adult filariae in the human system. As shown by Acton and Rao (1929a) there is a distinct evidence of the production of a toxin liberated by the adult worm during the process of discharge of embryos. The eosinophilia exhibited by persons with microfilariae in the peripheral blood in contrast with those whose blood is negative for microfilariae is an evidence of the presence of the toxin. The liberation of the toxin therefore, is clearly the cause of the urticaria.

In this connection it is interesting to note that the periodicity of urticaria in the cases discussed throws some light on the embryo-laying habits of *Filaria bancrofti* in the lymphatics. Fairley and Liston (1924) working with *Filaria medinensis* have shown that at the time the worm lays its embryos, there is an occurrence of eosinophile granulation tissue reaction round the worm. The same factor has been observed by the present authors during their studies on "Kataphylaxia in Filariasis" (*loc. cit.*). In the paper referred to, it was shown that there is a distinct eosinophile granulation in the lymphatics in the region of the anterior end of the worm where the vulva is situated, while it is not perceptible in the tail region. This gives further support to the view expressed here that the urticaria is due to the toxin liberated during the discharge of the embryos by the parent worm.

By a proper study of the incidence of the attacks of typical cases of filarial urticaria, it should be possible to obtain a definite knowledge of the life-history of the adult worm in the human system, as to whether embryos laying goes on continuously or whether there is any periodicity.

Not all cases with filarial infection exhibit urticaria. The reason for this is that a hypersensitiveness towards this toxin is developed. The susceptibility of the individual is mainly responsible for this manifestation and affects only

those individuals who are sensitive to this particular toxin, as was shown by Acton and Chopra (1924) in regard to other allergic manifestations.

SUMMARY AND CONCLUSIONS.

(1) A detailed study of the correlation of urticaria to filariasis was undertaken.

(2) Seven typical cases of urticaria which were observed during the period are described.

(3) These cases were negative to all the tests used in diagnosing the cause of urticaria, but had microfilariae in their peripheral blood. It is therefore established that urticaria in these cases is due to filarial infection.

(4) The toxin liberated by the adult female worm during embryo-laying is responsible for the manifestation of urticaria.

(5) Urticaria is not seen to be a universal phenomena of filariasis. Individual susceptibility, as in other cases of allergy, evidently accounts for its restricted occurrence.

SOME OBSERVATIONS ON THE INCIDENCE AND MORTALITY FROM ECLAMPSIA IN CALCUTTA, AND ITS PREVENTION.*

By GRACE STAPLETON, M.D., B.S., W.M.S.
Medical Superintendent, Dufferin Hospital, Calcutta.

At the Congress of the Far Eastern Association of Tropical Medicine held at Calcutta in December 1927, a paper was read by Dr. Margaret Balfour, Research Worker at the Haffkine Institute, Bombay, on the diseases of pregnancy, and in it statistics were quoted of the incidence of the various diseases in different parts of India. Figures were obtained from the records of nearly seven thousand cases which were treated in one year at certain hospitals in Bombay, the Government Maternity Hospital, Madras, and the Eden Hospital, Calcutta. Out of this total, 128 cases of eclampsia were recorded, 50 per cent. being from Calcutta with a death rate of 31.2 per cent., as can be seen in the following table:—

Place.	Eclampsia rate per 1,000 births.	Case mortality. Per cent.
Bombay ..	9.7	12.0
Madras ..	13.3	12.8
Calcutta ..	41.0	31.2

* Being a paper read at the Medical and Veterinary Section of the Indian Science Congress, Allahabad, January, 1930.

Even allowing for the fact that Madrassi women are probably more ready to go to hospital for a normal confinement than those in Bengal, these figures show that there is a very high incidence and a severe type of the disease in Calcutta, the reason for which has still to be investigated. Apart from the actual eclamptic fits, many cases of toxæmia of a lesser degree occur, these being so common that the popular opinion among the women is that œdema and malaise are part of normal pregnancy and so can be disregarded and given no treatment—hence the most disastrous results frequently ensue.

Recently a closer investigation of all the eclampsia cases which were treated at the Lady Dufferin Victoria Hospital, Calcutta, during the years 1927 and 1928 was made. The incidence was found to be rather higher than in the neighbouring Eden Hospital, for 65 cases were seen in that time out of a total of about 1,200 deliveries. Apart from this, certain striking facts emerged:—

(1) That a very large majority of the cases were primigravidae.

(2) That it was mainly a disease of young women of 20 years of age or under.

(3) That the death rate among these younger women was double that among the older ones.

The following tables illustrate this:—

Parity.	Number of patients.	Deaths.	Percentage of mortality.
Primigravidae	53, i.e., 81.5%	11 (plus† 2)	24.5 (20.75)
Multigravidae	12, i.e., 18.5%	2	16.6 %

† Two cases taken home almost moribund.

Age of patient.	Numbers.	Number of deaths.
14 years	2	0
15 "	8	2
16 "	10	3
17 "	6	3
18 "	5	0 (plus 1)
19 "	6	1
20 "	13	2 (plus 1)
21 "	0	0
22 "	2	0
23 "	1	0
24 "	2	0
25 "	4	1
26 "	1	0
27 "	0	0
28 "	1	1
30 "	2	0
32 "	2	0

Another fact that was brought out by the study of this series of cases was that the prognosis was far more serious when fits occurred in the latter

months of pregnancy than when they began with ordinary labour. The figures are as follows:—

Times of onset with reference to labour.	Number of cases.	Deaths.	Percentage death rate.
Before labour ...	15	6 (plus 1)	47 % (40)
With or during labour.	45	6 (plus 1)	15.5% (13.3)
After labour ..	5	1	20 %

The number of cases in the last line are too small to be of great significance. It was further noted that out of 16 cases who came in for labour and developed eclampsia in hospital, only one died and that was after 6 post-partum fits.

Promonitory symptoms occurred in at least three-quarters of the cases, especially œdema and headache, the former in 33 and the latter in 27 of the series, but headache was very often a very late symptom and came on in 11 of the cases only a few hours before the commencement of the fits. In 12 others it had been complained of at times varying from one week to two months previously. The œdema was more often of long duration, having lasted from one to four months in more than half the patients and in two cases throughout pregnancy, while in 13 others it had been present less than 14 days. Other prodromal symptoms were of comparative rarity, for a history of vomiting was given only in four cases; scanty urine, fever and frequent stools each in two; and drowsiness, stupor, loss of appetite, poor sight, abdominal pain and marked constipation each in one instance.

Symptoms lasting over a week had been present in about half the cases and yet there was no evidence that treatment had been received by any of these patients.

Preventive measures.—In the light of the above figures, surely it is time that the subject should be more seriously considered by the medical profession and the health authorities in this country. We know that the disease can largely be prevented by ante-natal care, so much so that in those countries where ante-natal clinics are properly and widely organized and medical advice is sought regularly by the majority of pregnant women, eclampsia is rapidly becoming an uncommon disease. The lives lost here in India are those of otherwise healthy young women, over whose recent marriage a large amount of wealth has been spent. If general practitioners would combine together, especially in the districts where the disease is most common, and give warning to the heads of all households which they attend and where there are young married women, of the possibility of the disease, and the need for constant medical supervision and dieting during pregnancy, especially for the last three months, then the disease would become much less frequent. For the poor who cannot afford to call a doctor often or to pay for frequent testing of the urine for albumen, systematic house-to-

house visiting should be instituted by municipal health visitors, midwives or voluntary social workers, and the pregnant women encouraged to attend one of the free ante-natal clinics now attached to women's hospitals and maternity homes or welfare centres, and there they would have thorough examination and receive advice should the least deviation from normal be detected at any time.

It is ignorance that is largely responsible for the existing state of affairs, and households who have once experienced one of these tragedies in their midst, will soon respond to promises of help on future occasions, even if it does mean breaking down many old customs; and others will follow once the lead is given. At the British Medical Association Annual Meeting held at Manchester in July 1929, the suggestion was brought forward by an obstetrician from one of the leading London hospitals that the toxins responsible for this disease, could be prevented from developing or neutralized as they were formed, if sufficient alkalies were regularly given from as early as the second or third month of pregnancy to keep the body tissues at a certain degree of alkalinity, the degree being checked by laboratory tests on the blood and urine. He had treated a series of patients who had suffered from eclampsia or lesser toxæmia during the previous pregnancy on these lines, as well as by careful dieting, and though as much as an ounce and a half of alkali in the form of potassium citrate and sodium bicarbonate might be required daily yet he had had very favourable results both to the mothers and to the infants. His number of cases was small, but considering the great damage that the disease is responsible for in this country, it would be worth while trying the experiment on a larger scale, even if conditions were such that the amount of alkali required could not often be checked by laboratory tests.

From a social standpoint, the fact that it is the young primigravidae who suffer most from this toxæmia could be used as a strong argument in favour of raising the marriage age and the time of consummation of marriage until the girl has completed her physical growth, for in the year November 1927-1928, out of the 34 girls of sixteen years and under who were admitted to the Calcutta Dufferin Hospital for their first confinement, no less than 11, i.e., 32 per cent. had eclampsia, to say nothing of those who had lesser signs of toxæmia.

THE EFFECT OF SANOCRYSIN ON THE EFFICIENCY OF THE LIVER.

By T. A. HUGHES, M.A., M.R.C.P., D.P.H.,
MAJOR, I.M.S.,

Professor of Clinical Medicine, King Edward Medical College, Lahore,

and

KHAZAN SINGH MALIK, M.Sc.

It is now agreed that the toxic symptoms produced by sanocrysin in tuberculous patients

are not due to cleavage products of the tubercle bacillus, but are the result of metallic poisoning. The fact that metallic compounds are taken up by the liver and retained for a considerable period (Rolleston and McNee, 1929), raises the question as to whether this drug interferes with hepatic function. It has been shown that intravenous administration of colloidal preparations of lead produces focal necrosis of the liver (Cunningham and Datnow, 1929), and that large subcutaneous doses of aluminium cause hepatic injury (Underhill *et al.*, 1929). Cushny (1924) states that nausea, vomiting and diarrhoea, persisting for several days, follow the intravenous injection of large doses of the double chloride of gold and sodium in dogs. The animals eat nothing, lose weight, and die in a week or more after the injection, ulcers are found post-mortem in the stomach and intestines. This author does not mention the occurrence of lesions in the liver. That sanocrysin damages the cells of the kidney is shown by the fact that albuminuria occasionally follows its administration. The observations of Sevend Lomholt (1926) led him to the conclusion that sanocrysin "produces toxic effects in the organism which are not unlike those caused by other heavy metals, and that there is therefore the same danger of poisoning through accumulation of the metal."

In five patients (Table I), suffering from chronic pulmonary tuberculosis the ordinary lævulose tolerance test was done $\frac{1}{2}$ to 1 hour after the intravenous administration of sanocrysin in

doses varying from 0.05 gm. to 0.5 gm., a control test having been carried out in each case on the previous day. One of the patients had already been on sanocrysin treatment, but this had been stopped some weeks before the test. Estimations of the bilirubin content of the blood serum were also made two hours after giving sanocrysin, as well as on the day before. In six cases (Table II), suffering from diseases other than tuberculosis, the effect of 0.1 gm. of sanocrysin on the ability to store 50 grms. of glucose was similarly observed. The sugar was given before the morning meal immediately after the drug. In a third series of six patients (Table III), two of whom (Nos. 1 and 6) were tuberculous, the blood sugar was estimated at half-hourly intervals up to $2\frac{1}{2}$ hours after the intravenous injection of 0.1 gm. of sanocrysin. No carbohydrate was administered, the object being to see whether the gold preparation interfered with the maintenance of the blood sugar level by the liver. In none of the subjects experimented on were vomiting or diarrhoea produced. Albuminuria occurred in one patient and a rise of temperature in two.

Most of the cases had high initial blood sugar and from the results in Table II it is probable that a large proportion had defective power to store glucose. Nevertheless, the glucose and lævulose curves after sanocrysin were no worse than in the control experiments. In some instances there was actually an improvement in carbohydrate tolerance. Further, the figures in

TABLE III.

Fasting blood sugar at half-hourly intervals after 0.1 gm. sanocrysin intravenously.

		Initial.	$\frac{1}{2}$ hour.	1 hour.	$1\frac{1}{2}$ hour.	2 hours.	$2\frac{1}{2}$ hours.
(1) M. S., æt 30 ..	Tuberculous pleurisy ..	137	137	135	127	117	122
(2) R. B., æt 35 ..	Ankylostomiasis ..	146	137	118	125	126	131
(3) S. S., æt 20 ..	Chronic malaria ..	141	143	141	133	139	..
(4) E. S., æt 20 ..	Convalescent from broncho-pneumonia.	156	139	159	139	159	141
(5) H. R., æt 50 ..	Syphilis ..	156	156	171	166	150	156
(6) W. S., æt 22 ..	Unilateral pulmonary tuberculosis. Febrile. temperature 99° daily.	150	152	166	159	177	177

Table III do not indicate any marked constant effect of sanocrysin on the fasting blood-sugar level. One may, therefore, conclude that this preparation did not exert any deleterious effect on the glycogenic function of the liver in these patients. The ability of the liver to excrete bile pigment would also seem not to have been disturbed in the patients in Group I. The observations do not, of course, prove that there is no hepatic derangement when vomiting and other gastro-intestinal symptoms follow sanocrysin administration, but they show that interference with the liver function does not generally result from the administration of small doses of this drug.

CONCLUSION.

Sanocrysin administered intravenously in doses varying from 0.05 gm. to 0.5 gm. was found not to damage the glycogenic function of the liver in 17 patients, 6 of whom were suffering from pulmonary tuberculosis. In five of the latter the bilirubin content of the blood serum was estimated 24 hours before and 2 hours after

giving the drug. No significant change was observed in any of the patients.

Our thanks are due to Dr. Lal Chand Khanna, Professor of Physiology, King Edward Medical College, Lahore, for permission to work in his laboratory, and to Drs. Aman Ullah Khan and Shujaat Ali, for assistance during the investigation. The expenses of the research were defrayed by the Indian Research Fund Association.

THE VALUE OF PHRENIC-EXAIRESIS IN THE TREATMENT OF PULMONARY TUBERCULOSIS.*

By C. FRIMODT-MOLLER, M.B., CH.B. (Copenhagen),
Medical Superintendent, The Union Mission Tuberculosis
Sanatorium, Arogyavaram, near Madanapalle,
South India,

and

DAVID V. GNANAMUTHU, B.A., M.B., B.S. (Madras),
Assistant.

History of the operation.—In 1911 Stuertz suggested phrenectomy as an operation to be used in the treatment of pulmonary tuberculosis, but at that time this operation attracted only little attention. Since 1922 when Goetze and Felix reported encouraging results after evulsion of the nerve, the phrenic-exairesis operation has gained much ground all over the world, especially during the last few years.

The reason why a simple cutting of the phrenic nerve often has no permanent effect, was shown by Felix to be due to the existence, in from 25 to 30 per cent. of cases, of an accessory phrenic nerve which is not destroyed by the mere cutting of the main nerve. Later researches by other authors have supported the work of Felix. By anatomical studies on 17 cadavers Ruhemann(1) found the accessory nerve to be regularly present, and Plenk and Matson(2) found this "neben-phrenicus" in 29 out of 48 cases studied. In 1925 Yano(3) found the accessory branch present in 17 out of 22 bodies, and Kutamanoff(4) found that the nerve was double in 69 cases out of 100 anatomical preparations examined by him. Besides the accessory phrenic nerve, there exist also subclavicular and sympathetic anastomoses. Morriston Davies(6) describes a summary of abnormalities observed by him during operations. A more radical procedure than a simple cutting of the main nerve was therefore found to be necessary in order to destroy the accessory branch and the possible anastomoses. The first evulsion of the nerve, by which this destruction is obtained, was performed by Felix(6), the operation being suggested by Thiersch.

The physiological effect.—The effect of the phrenic exairesis operation is that the paralyzed hemidiaphragm occupies a higher position in the thorax. The elevation may be on the right side from 4 to 8 cm. and on the left from 2 to 4 cm.(6). The rise is increased during the ensuing weeks. Goetze(7) states that the paralyzed diaphragm may continue to rise for six months. This should be borne in mind, as it is one of the reasons why the full benefit of phrenic-exairesis is often seen only after several months.

During ordinary respiration the paralyzed dome of the diaphragm remains immobile. By the high and immobile position of the hemidiaphragm the lung volume is said, in favourable cases, to be reduced, not infrequently, by one-quarter to

one-third. The result of this reduction is a partial collapse of the lower lobe and a diminished respiratory activity, especially at the base. The operation has the effect of partly immobilizing the lung, and phrenic-exairesis produces therefore an effect similar to that produced by artificial pneumothorax, although to a less degree.

The technique.—Under local anaesthesia usually with 10 c.c. of a half per cent. solution of novocain with adrenalin, an incision of from one to two inches in length is made from the middle of the posterior border of the sterno-mastoid muscle to the middle of the clavicle. The phrenic nerve is found on the scalenus anticus muscle beneath the fascia, traversing this muscle from without inward and downward entering the thorax behind the subclavian vein. When the nerve has been dissected totally free, it is divided and slow traction is applied on the peripheral end, by which procedure the nerve is gradually pulled out of the thorax. The patients often feel some pain over the epigastrium or occasionally in the shoulder when the evulsion is performed.

Although the operation is a comparatively minor one, it is not without risk. Severe hæmorrhages have been described to occur by cutting of veins with the subsequent danger of air embolism. In one of our cases the jugular vein was mistaken for the scalenus muscle and opened. The same mistake is also reported by Gravesen(8) in which case air was sucked in. The vein was, however, in both cases ligatured and no symptoms of air embolism were observed. Morriston Davies(6) mentions four occasions where the vagus nerve has been mistaken for the phrenic, with fatal results each time. He draws attention to the possibility that the traction on the nerve trunk may lead to rupture of the pleura or of the lung if the pleura is attached to the surface of it. Such a rupture of pleura occurred in one of our cases with a fatal result. This was due to the collapse of the lung in the side operated upon by a sudden rush of the air through the ruptured pleura, while the other lung was already collapsed by pneumothorax treatment with recent refill, and in this way both lungs became collapsed at the same time. Temporary heart failures, dyspnœa, and hæmoptysis are mentioned as operative complications, but we have not experienced any of these. Copious vomiting and severe shivering just after the operation have occurred in a few of our cases.

The length of the nerve secured by the evulsion seems to be of less consequence. We have observed some of the best results of the operation in cases where only one inch of the nerve was removed, while in some cases no benefit was obtained where even 13 inches, or practically the whole peripheral end of the nerve was pulled out.

The first 76 phrenic-exairesis operations at the sanatorium were performed by Dr. R. H. H. Goheen and the last 28 by Drs. P. V. Benjamin and David V. Gnanamuthu.

* Being a paper read at the Medical and Veterinary Research Section of the Indian Science Congress, Allahabad, January, 1930.

Indications.—The phrenic-exaïresis operation was originally performed chiefly as a preparatory operation to thoracoplasty, with the object of testing the ability of the other lung to stand the strain of the increased respiratory work to be borne by it, or with the object of giving the patient an opportunity of readjusting himself to the changes in the circulation and respiration resulting from the sudden collapse of one lung after thoracoplasty. During last year phrenic-exaïresis has, however, gained much ground as a substitute for pneumothorax treatment in cases where either pleural adhesions are preventing this treatment, or where it is contra-indicated on account of too extensive lesions in the less diseased lung. Generally speaking it can be said that the indications for phrenic-exaïresis are the same as for pneumothorax treatment, although the indications can be extended also to cases unfit for pneumothorax treatment where, for some reason or other, thoracoplasty is not advisable.

Several authors have argued that phrenic-exaïresis should be used as a substitute for pneumothorax treatment only in those cases where the lesion is confined to the basal part of the lung, as the paralysis of the hemidiaphragm could not have any effect on lesions in the apex of the lung. Holmbo(9) declares this argument to be purely theoretical and not substantiated by clinical experience, as good results have been obtained in cases with apical lesions, while bad results have been observed in cases with basal lesions. Morriston Davies(5) states that experience has shown that the upper part of the lung is unquestionably affected in certain cases. This was demonstrated by x-rays showing diminution in cavities near the apex following immediately on phrenic evulsion. He quotes a number of well-known authorities who all emphasize this point, and he gives his own experience in support of it, to which we can also add ours.

There has been a considerable controversy on the question of the use of the phrenic-exaïresis operation as an accessory to pneumothorax treatment in order to supplement an incomplete pneumothorax. Gravesen(10) expresses himself strongly against this use of phrenic-exaïresis, having obtained chiefly negative results, and argues that the paralyzed diaphragm will give way to positive intrapleural pressure and in this way prevent a proper collapse being established. Morriston Davies(5), however, draws attention to a statement by Zadek in which it is pointed out that the paralyzed dome prevents the downward displacement of hemidiaphragma unless excessive intrapleural pressures are used in collapsing the lung by the pneumothorax. The experience of Morriston Davies is that good results from phrenic-exaïresis were often obtained in cases of incomplete pneumothorax. The intervals between the refills were lengthened considerably, and he states that "excellent results" were seen in some cases, while other cases were "considerably benefited."

We share the experience of those who report that good results are obtained by phrenic-exaïresis as a supplement to pneumothorax treatment. In one case where the fever and the presence of tubercle bacilli in the sputum persisted after eleven refills, the fever disappeared two weeks after the phrenic-exaïresis operation, and the bacilli three months later; cough and sputum soon became less, the weight increased and the lung improved considerably. The patient, after twenty-five more refills, was discharged as "much improved." In two other cases a similar striking improvement was observed, while marked improvement was obtained in about half the number of cases where phrenic-exaïresis was used as an accessory to pneumothorax.

In India where it is so difficult for patients to continue pneumothorax outside the few places where this treatment is given, the phrenic-exaïresis operation should be used also in many cases with a complete pneumothorax when the patient has to leave without prospect of receiving further refills. The phrenic-exaïresis operation will produce a permanent minor collapse preventing the lung from a too sudden and a too extensive re-expansion.

The opinion of a few authors that phrenic-exaïresis should be done practically in all cases treated with pneumothorax is not shared by a great number of authorities. In this connection it should be pointed out that during a complete pneumothorax the lung can be allowed to re-expand if the other lung shows signs of becoming extensively attacked, while a collapse produced by phrenic-exaïresis is permanent. We have observed two cases where this permanent collapse proved very detrimental as the lesion in the other lung increased in activity.

Analysis of our results.—At the sanatorium 104 patients have been operated on. From the analysis are excluded 4 cases operated on in connection with thoracoplasty, and 8 cases in which the time since the phrenic-exaïresis has been less than one month.

Out of 92 cases left for analysis 1 was in the I stage, 7 were in the II stage and 84 in the III stage of pulmonary tuberculosis. The patients are divided into group A, comprising those on whom the operation was performed as accessory to pneumothorax-treatment, and group B, comprising those on whom it was done as the sole procedure.

A. Thirty-seven patients who did not derive the full benefit of pneumothorax treatment due to adhesions present were operated upon after having received from 10 to 35 refills. Of these patients one was in stage II C, 5 in III A, 10 in III B, and 21 in III C.

Fever disappeared within from one to six weeks after the phrenic-exaïresis operation in 11 patients out of 24 of this group who had fever at the time of operation. Among 8 patients out of 15, who later on became "much improved,"

the fever present before the operation disappeared in 7 out of the 8 cases, within six weeks.

Tubercle bacilli disappeared from the sputum within about 6 weeks after the operation in 14 out of 31 cases having tubercle bacilli in sputum at the time of operation.

Cough and sputum became less after the operation in 12 out of the 37 cases, and *the weight* increased in 4 cases while the weight was decreased only in one case in this group.

End results.—Out of the 5 cases in stage III A, 2 were "much improved" and 2 "improved"; out of the 10 in III B, 5 were "much improved" and 4 "improved"; and out of the 21 in III C, that is in the stage with the worst prognosis, 8 or 38 per cent. were "much improved" and 5 "improved."

B. Fifty-five patients had the operation as the sole procedure. Out of these one was in stage I, 6 in stage II, 7 in III A, 13 in III B, and 28 in III C.

Fever disappeared within from one to six weeks after the operation in 12 out of 39 cases which had fever at the time of operation. In 8 out of 19 which later on became "much improved," the fever disappeared in 7 out of the 8 cases.

Tubercle bacilli disappeared from the sputum within about 6 weeks after the operation in 12 out of 51 cases having tubercle bacilli in the sputum at the time of operation.

Cough and sputum became less after the operation in 28 out of the 55 cases, and *the weight* increased in 12 cases, while it decreased in 19.

End results.—The one patient in stage I and the 3 out of 6 in stage II were "much improved." Out of the 7 patients in III A, 4 were "much improved" and 1 "improved"; out of the 13 in III B, 5 were "much improved" and 4 "improved"; and out of 28 in III C, 6 or 21.4 per cent. were "much improved," and 7 "improved."

We have not observed any difference worth mentioning in the results obtained in the patients having the operation on the right side compared with those having it on the left.

CONCLUSIONS.

Our experience is that the phrenic-exaeresis operation is of value in the treatment of selected cases of advanced pulmonary tuberculosis, both in those cases where the operation is performed as an accessory to an incomplete pneumothorax, and also in those cases where the phrenic-exaeresis is the sole procedure. In India where pneumothorax treatment is so difficult to continue when the patients have to leave the few places where it is given, the phrenic-exaeresis should be performed also in cases with a complete pneumothorax at the time the pneumothorax treatment is stopped earlier than desired, in order to prevent a too sudden and a too extensive re-expansion of the collapsed lung.

SOME SURGICAL ASPECTS OF TUBERCULOSIS.*

By ERNEST F. NEVE, M.D., F.R.C.S. (Edin.),
Mission Hospital, Kashmir.

AN eminent authority on tuberculosis, Sir R. W. Philip wrote a few years ago, "The more one sees of tuberculosis, and the distressing aftermath of operative interference, the more one is constrained to advise the surgeon to withhold his hand" (1). Now no doubt there may be complicated cases, with diffuse or varied forms of infection. Incomplete surgical operations can at best only result in local palliation. Perhaps physicians see many cases complicated by general infection, including some in which surgeons have failed to give relief, or have attempted too much. But even in the treatment of pulmonary tuberculosis great advances have been made. Diagnosis has been greatly facilitated by the use of x-rays, bronchoscopy and the use of iodized oil. It is only necessary to mention the excellent results obtained by artificial pneumothorax, resection of ribs for empyema, thoracoplasty for chronic pulmonary phthisis and partial pneumonectomy (2). Still even now, in the presence of acute phthisis, surgery is almost powerless.

In glandular tuberculosis the case however is very different. In the plains of India, bovine tuberculosis is relatively uncommon, only about 3 per cent. of the slaughtered cattle showing traces of it. But there the herds live an open air life. In Kashmir, with its intensely cold winter, necessitating the shutting up of cows in sheds, which are too often absolutely without ventilation, bovine tuberculosis is more common.

* Being a paper read at the Medical and Veterinary Research Section of the Indian Science Congress, Allahabad, January, 1930.

and this accounts for the number of cases with which we have to deal.

In 1901 we published a record of 700 cases of tuberculous glands,(3) and since then the total has mounted up to 3,000 operations for this condition.

There must be some difference between the type which we see and that met with in Europe. The Berne Hospital Reports record a death rate of 29 per cent. in 692 cases, the lungs, intestines, meninges or kidneys being subsequently affected(4). With us the post-operative mortality has been very low, under 0.5 per cent., debility, tuberculous meningitis and tuberculous ulceration of the bowel being the chief causes. Until recently, the absence of associated pulmonary disease was remarkable. Now, occasionally, we do meet with it. In 1923, curiously enough, in one month, we had two cases in which there was slight hæmoptysis, some days after operation, respectively for tuberculous glands of the neck, and ankle joint disease. Such cases, which are rare, do not necessarily invalidate the belief that in Kashmir, phthisis pulmonalis and tuberculosis of lymph-nodes are usually due to different types of infection; for separate lung infection might have been activated by disturbance of bovine foci at the time of operation. During the first twenty years that I practised in the Valley of Kashmir, its extraordinary freedom from pulmonary tuberculosis was a constant source of surprise. In those days, especially from 1880-90 communications with India were not easy, and the difficulties were sufficient to stop invalids from using Kashmir as a health resort. Now this is all changed by motor traffic, and every year many phthisical patients are sent here for the benefit of the climate.

There can be no doubt that many cases of tuberculous lymph glands are strictly localised and can be eradicated surgically. In Kashmir, wounds of fingers and toes with creeping tuberculous infection of lymph-glands are not uncommon and such cases call imperatively for early excision. This is usually followed by complete recovery. So also infection may break through the first line of defence—the tonsils and adenoid tissue(5). Indeed our experience here leads us to think that infection of lymph-nodes is due to local and not to blood transmission. Thus prompt surgical operation is usually followed by recovery. This does not mean that very early cases should not be dealt with medically, while being kept under observation. Sir Robert Philip lays great stress on the importance of watching children, especially in families with a tuberculous history. Anticipatory detuberculization by the percutaneous method is important and even if glandular enlargements are present, they may be progressively reduced. Heliotherapy is most valuable. Sir Henry Gauvain's work in demonstrating the amenability of surgical tuberculosis to wise treatment under favourable conditions

and if sufficient time is available is well known. But the danger, of course, is lest patients should not remain under observation, or lest they should have insufficient patience and resort to other treatment while the glands continue to increase in size. Creeping infection may thus involve fresh areas, so that patients may return with masses of enlarged glands, for instance, on both sides of the neck, and even in the axillæ. Some of these nodes may have softened and suppurated. There may even be induration, and sinuses with septic discharge and much resulting deformity. Operative treatment may then be extremely difficult, even if advisable.

For this reason conservative treatment must be used with caution and at once abandoned if there is evidence of progression or softening. I remember a case, many years ago in which operation, for some reason was deferred although a lymph-node in the neck was soft and fluctuating. The patient suddenly developed acute phthisis. At the same time the node diminished in size and there was grave doubt as to whether a rupture into the cellular tissue may not have started or activated the disease. This case, which was in England, may however not have been of bovine origin. The exact pathology of these glands is still not quite clear. It seems probable that the majority are due to bovine infection. Certainly the danger from unboiled milk of tuberculous cows must be very real. It is disquieting to be told that one quarter of the specimens of milk examined in London were tainted with the tubercle bacillus(6). What must be the condition in Kashmir?

As a matter of fact, most of the cases of enlarged lymph nodes which come to us for treatment are already so advanced as to leave no doubt as to the wisdom of their immediate removal. Early cases, before the softening of the glands has proceeded too far, are very easy to deal with. I have removed as many as 58 from one patient, and if not adherent and not mere bags of pus they may shell out almost like potatoes. On the other hand soft adherent glands, especially if embedded in firm adhesions or adherent to main vessels entail tedious dissection and prolonged operation. Indeed sometimes, although not an ideal method, recourse must be had to evisceration. The indications for this are very superficial glands suppurating and with thin adherent skin over them, or on the other hand deep adherent soft glands especially if in close contact with main vessels. The careful use of a sharp spoon and iodoform emulsion often gives very satisfactory results. Even in cases where septic sinuses lead to disintegrating gland masses, it is nevertheless sometimes possible to excise the whole and this should always be one's aim. With regard to operative technique, it is sufficient to say that incisions should give free access and not leave scars in conspicuous positions. The spinal accessory nerve should be sought and spared and branches of the cervical plexus left intact as far

as possible. With care the internal jugular vein is seldom in danger, but small branches cut near the main trunk may give trouble. Nodes under the sterno-mastoid attacked from the posterior triangle may be adherent and in traction upon them the danger of wounding a displaced internal jugular vein must be remembered. There is one other point, and that is that only obviously diseased glands should be removed. It is undesirable to deprive the lymph circulation of valuable gland filters if they are still working.

It is difficult to obtain accurate results, but on a conservative estimate 75 per cent. of our 3,000 cases were cured although some of these, possibly 10 per cent., might need further operations for other glands. Some 15 per cent. were distinctly improved but had slight discharge or incomplete removal of all diseased glands. About 10 per cent. left hospital with discharging sinuses and other signs of tuberculous disease and 0.5 per cent. died after operation in hospital. Such results encourage the surgeon not to "withhold his hand."

Tuberculous bone and joint surgery also hardly needs holding of a brief on its behalf. Especially during the past quarter of a century have the results shown manifest improvement. It is true that in the East there are still too many instances of cases first coming to the surgeon when there are already one or more sinuses communicating with a septic joint. In the case of the ankle, it is seldom that the necessity for a Syme's amputation can be avoided. This is also the case with regard to tarsal disease, where the bones are often so soft and fatty that operations for caries are usually doomed to failure. An exception perhaps is the os calcis which can sometimes be removed with success. In septic tuberculous disease of the elbow, excision still holds its own. In the knee arthrectomy if done early saves many a limb. My practice is to save the crucial ligaments, removing all accessible synovial membrane and treating the rest with a sharp spoon, and friction with a swab carrying iodoform emulsion.

In the case of early joint disease, exposure to the sun's rays and the careful use of tuberculin gives excellent results if time is available. But with hospital patients early arthrotomy, followed if there is no marked improvement, by arthrectomy saves an immense amount of time and gives results which are more rapid and usually equally good.

In the case of joints, bones and abscesses, the value of early evacuation of pus, closure of the wound, and rest with heliotherapy and the use of well-known auxiliaries, e.g., tuberculin, Bier's bandage, cupping, etc., has been demonstrated, and the results of present day surgical treatment in tuberculous adenitis, bone and joint disease and cold abscesses are therefore in gratifying and in marked contrast to the conditions which existed even at the beginning of this century.

THE SIGNIFICANCE OF SPIROCHÆTES IN THE SPUTUM, WITH SPECIAL REFERENCE TO PULMONARY TUBERCULOSIS.*

By P. V. BENJAMIN, M.B., B.S. (Madras),
 Senior Assistant, Union Mission Tuberculosis Sanatorium, Arogyazaram, near Madanapalle, South India.

Historical summary.—A good deal has been written in recent years about bronchial and broncho-pulmonary spirochætos. As early as 1867 Leyden and Jaffe(1) discovered spirochætes in the sputum in cases of putrid bronchitis, and also at necropsy in gangrenous lung tissue. In 1905 Rona(2) reported the presence of spirochætes in two cases of pulmonary gangrene. But it is only since Castellani's(3) claim in 1906 of the discovery of a new tropical disease, which he called "broncho-spirochætos," that extensive investigations have been made on this subject. Since then, reports of cases from all parts of the world have appeared, including those by Waters(4) from India, Lesslar and Kanagarayer(5) from Malaya, Sinclair(6) from the Philippines, Schwarz(7) from Egypt, Violle(8) from the Continent, Campbell Faill(9) from England, and Smith(10), Pilot(11) and co-workers from the U. S. A., showing that "broncho-spirochætos" is not a "tropical" disease.

The impression one gets from the different reports about the morphology of the *Spirochæta bronchialis* and the nature of the disease caused by that organism is rather confusing.

According to Castellani(12), the spirochæte is extremely pleomorphic, its length varying from 3 to 30 microns, its breadth from 0.2 to 0.6 microns. The number of coils also varies from 3 to 10. As Knowles(13) rightly puts it, "Castellani's original description of *S. bronchialis* is such that it would be almost impossible to recognize this 'species' even if one came across it." Fantham(14), who has studied the

* Being a paper read at the Medical and Veterinary Research Section of the Indian Science Congress, Allahabad, January, 1930.

morphology of this organism, supports Castellani's findings, and considers that this spirochæte is different from the ordinary ones found in the mouth. On the other hand Smith (10), Vincent (15), Schwarz (7) and Mühlens (16), among others, hold the view that the so-called *Spirochæta bronchialis*, is in reality, one of the ordinary spirochætes found in the mouth. According to Smith (17), the spirochætes and fusiform bacilli grown in culture, from the lung tissue of those who had died of spirochætal disease of the lungs, were morphologically identical with those found in the mouth. Bezançon and Etchegoin (18) take still a third position. They think that the spirochæte that causes blood in the sputum is neither the *Spirochæta bronchialis* of Castellani, nor one of the mouth spirochætes as others claim, but is one that is morphologically intermediary between the two.

This confusion of findings is probably due to the fact that the differentiation of the spirochætes found in the sputum from those found in the mouth is very difficult. It has to be remembered that fusiform bacilli are always found in association with spirochætes of the mouth, and when spirochætes are found in sputum, the fusiform bacilli are also nearly always present. The consensus of opinion to-day, as Baldwin (19) and his co-workers point out is that the spirochætes that produce broncho-pulmonary diseases, are mostly those found in the mouth, namely, *Treponema microdentium*, *Treponema macrodentium*, and *Spirochæta vincenti*, and not a different organism as is claimed by Castellani and others.

Castellani's (12) own description of the disease "broncho-spirochætosis" is extremely vague. Since his publication in 1906 numerous observers have reported on the subject and have claimed the spirochætal infection as the cause, or as one of the causes of a great variety of broncho-pulmonary disorders, such as hæmoptysis in pulmonary tuberculosis, secondary mixed infection in tuberculous cavities of the lungs, bronchitis, certain cases of unresolved pneumonia, bronchiectasis, lung abscess, and lung gangrene.

This question regarding the significance of spirochætal infection in relation to most of the conditions mentioned above has been re-investigated among the patients in the Sanatorium.

Technique.—The examination of the sputum for spirochætes is influenced by the fact that spirochætes in association with fusiform bacilli are normally present in the mouth. They were found by Pilot and Davis (11) in 82 per cent. of tonsils, and 32 per cent. of adenoids. In 100 of our patients in the Sanatorium whose gums and tonsils were examined for spirochætes and fusiform bacilli, these organisms were found in 93 per cent. of gums, and in 34 per cent. of tonsils. It is therefore important to avoid contamination from the mouth when examining the sputum for spirochætes and fusiform bacilli. To this end the mouth should be rinsed out as pointed out by several of the later investigators; and the throat gargled several times with a sterile mouth

wash, just before the collection of the specimen. Care should, in our opinion, be taken to see that the sputum is really coughed up from the chest, and expectorated immediately into a sterile Petri dish. When there is difficulty in bringing up the sputum from the chest by cough, there is a common tendency to clear the throat, and bring out the secretion from the posterior nares. Should the patient fail to cough up sputum from the lungs but bring out mucus from the posterior nares, care should be taken to rinse the mouth again, before another attempt is made to bring up the sputum.

When the sputum has been brought up in the proper way, a piece of the thick sputum about the size of a bean should be separated and washed at least five or six times with sterile normal saline as suggested by Smith (10). From the centre of this piece a small portion should be taken for smears. The smears should be made within half an hour after taking the sputum as it is stated that spirochætes disappear from sputum if kept too long. The smears should be dried in air, and fixed by Ringer's solution, not by heating. In our investigation the smears had been stained by both Fontana's stain and gentian violet, the latter chiefly used, since it is easier and as reliable as the former.

The presence of spirochætes in washed sputum.—The sputum of 331 patients in the Sanatorium has been examined without previous washing of the mouth and the sputum, and spirochætes were found in 196 or 59.2 per cent. On the other hand in the sputum of 170 patients examined after previous washing of the mouth and the sputum, spirochætes were found in only 3 or 1.8 per cent.

In the reports of some of the early workers, it has not been stated whether the precautions mentioned above in collecting the sputum have been taken or not. From the results given here it will be easily understood that those investigations in which these precautions were not taken are of no value whatever regarding the whole question of spirochætes in the sputum.

Spirochætal infection and hæmoptysis in pulmonary tuberculosis.—Sinclair (6) in the Philippines has examined the sputum of 410 cases of pulmonary tuberculosis for spirochætes and found these organisms in 256 or 62.4 per cent. He does not say whether any precautions were taken to avoid mouth contamination. It is significant that his percentage of positives closely corresponds to the percentage of 59.2 in the 331 tubercular patients examined by us without due precautions against mouth contamination. In 238 cases with hæmoptysis he found spirochætes in 182 or 76 per cent., and he concludes from this that the spirochæte is an important cause of hæmoptysis in pulmonary tuberculosis. Bezançon and Etchegoin (20) have found spirochætes in 43 out of 46 cases of hæmoptysis in pulmonary tuberculosis and they conclude that spirochætes are of clinical significance in tuberculous hæmoptysis.

Among the 170 cases examined by us where the sputum was collected with due precautions against mouth contamination, 162 patients suffered from pulmonary tuberculosis. In only one of these cases were spirochaetes found, while, as mentioned above, they were found in 59.2 per cent. of unwashed sputum of 331 tuberculous patients. Out of the 162 cases, 17 had hæmoptysis. In none of these were spirochaetes found.

Spirochaetal infection in cavities in pulmonary tuberculosis.—It is generally recognized that cavities in tubercular lungs are predisposed to secondary mixed infections with the ordinary pyogenic organisms such as streptococci, staphylococci and pneumococci, commonly found in the mouth (Hayes)(21). It is pointed out by Pilot(11), and his co-workers that spirochaetes and fusiform bacilli may also cause secondary infections in tubercular cavities along with the other organisms mentioned above. They say that foul-smelling sputum is the characteristic feature of this type of secondary infection.

Among the 162 tubercular patients, 122 showed signs of cavity in the lungs. None of these, except one, had spirochaetes in properly collected sputum. No spirochaetes were found even in the sputum of one who had foul-smelling sputum, while in the only case where spirochaetes were found the sputum was not foul smelling.

Spirochaetal infection and bronchitis.—From the description given by Castellani(12) of "broncho-spirochaetosis" the conclusion to be drawn is that the spirochaete is the cause of bronchitis where the sputum contains spirochaetes but no tubercle bacilli. Schwarz supports Castellani and Campbell Faill(9) confirms the finding of Castellani that spirochaetes are the cause of bronchitis with blood stained sputum. Unfortunately, it is not stated by these authors whether in their investigations due precautions had been taken against mouth contamination. Jackson(22), Campbell and Dyas(23), and Smith(10) report cases of acute bronchitis due to spirochaetal infection.

In the group of 162 cases examined by us there were 14 cases having bronchitis as a complication. Six of these had no tubercle bacilli in the sputum and 2 with tubercle bacilli in the sputum had hæmoptysis also. In the sputum of none of these 14 were spirochaetes found.

Spirochaetal infection and unresolved pneumonia and bronchiectasis.—It is stated by Smith(10), Pilot(11) and co-workers that the cause of certain cases of unresolved pneumonia and bronchiectasis, is spirochaetal infection. In 6 patients out of the 170 who had no tubercle bacilli in the sputum, but had signs in the lungs suggesting partially unresolved pneumonia or beginning bronchiectasis, no spirochaetes were found in the sputum collected in the proper way.

Spirochaetal infection and lung abscess.—Smith(17) believes that lung abscesses are usually caused by spirochaetal infection and gives experimental evidence.

Out of the group of 170 who were all sent to the Sanatorium as tuberculous patients, two were found to be suffering from lung abscess and not tuberculosis. In the sputum of these two cases spirochaetes were repeatedly found. This suggests that the finding of others, that lung abscess is caused by spirochaetes, is correct.

CONCLUSION.

Spirochaetes in association with fusiform bacilli must be considered normally present in the mouth. They were found in 93 per cent. of gums examined and in 34 per cent. of tonsils. The frequent presence of these organisms in the sputum is due to contamination from the mouth. The sputum of 331 patients has been examined without previous washing of the mouth and the sputum and spirochaetes were found in 59 per cent. of these cases. On the other hand in 170 cases where the mouth and the sputum were first washed, spirochaetes were found in the sputum in only 3 cases or 1.8 per cent.

Among these 170 cases, 162 were patients with pulmonary tuberculosis. Out of these 162 cases, 17 were complicated with hæmoptysis, 122 with cavities in lungs. Inasmuch as spirochaetes were not found in any of these 162 cases, except in one, it is not likely that spirochaetal infection has any significance regarding complications with hæmoptysis, or with secondary infections in cavities, in pulmonary tuberculosis.

Bronchitis was a complication in 14 of these 162 cases. Six of these had no tubercle bacilli in the sputum, and 2 with tubercle bacilli in the sputum had hæmoptysis also. In the sputum of none of these were spirochaetes found. Therefore it appears that spirochaetal infection is not significant in bronchitis.

Out of the 170 cases, 8 were non-tuberculous: Six of these were suffering from unresolved pneumonia or beginning bronchiectasis. In none of these were spirochaetes found. The remaining 2 were suffering from lung abscess, and in both of these spirochaetes were found repeatedly. This suggests that the finding of others, that lung abscess is caused by spirochaetes, is correct.

CONTUSION OF THE EYE AND COMMOTIO RETINÆ.

By M. D. ANKLESARIA, D.O.M.S. (Eng.), F.R.C.P.S.

(Bom.), M.R.C.S. (Eng.), L.R.C.P. (Lond.),

Honorary Ophthalmic Surgeon, Civil Hospital and Lecturer in Ophthalmology, B. J. Medical School, Ahmedabad.

CONTUSION of the eye and of its environs, i.e., injury direct or indirect by the transmission of concussion or shock, which does not produce rupture of the capsule of the eyeball causes a great variety of lesions. These lesions are best divided into two groups, those produced in the anterior segment, and those produced in the posterior segment of the eyeball. Among the latter is a condition known as commotio retinæ which, being very rare and interesting, deserves recording.

Mr. V. D., aged 26, a young Mahomedan, used to perform the feat of jumping over a distance of 25 feet in a Ford car in Parasram's Lion Circus which came over here for a short time. He used to have two slanting platforms placed about 25 feet apart, the ends of the platform facing each other being about 4 feet high, while their other ends sloped down to the level of the grounds on either side. He used to come in his old model Ford car at a certain speed and travelling up one of the inclined planes took a leap from the 4 feet high end into the air to a height of about 8 to 10 feet and then dropped on the higher end of the other plane, then sliding down the slope to the ground on the opposite side. On 27th July, 1929, while performing this feat he jumped all right on to the opposite platform, but, having taken a higher jump, instead of landing on the front wheels he landed on the radiator and the front of his car, with the result that the car turned turtle and he was buried underneath. He received a severe concussion injury to his head and scapula, and one of the radii of the broken steering wheel struck his left malar eminence and caused a big cut half an inch below the outer angle of his left eye. He was admitted to hospital suffering from the effects of concussion and shock. After two or three days, having partly recovered from these effects he complained of loss of vision in his right eye, though the wound was on the left side of the face. Major Candy, Civil Surgeon, kindly asked me to examine him. I did not then know much about his injury but found that there was some conjunctival ecchymosis, more in the left eye than

in the right, and that the right pupil was a little contracted and sluggish in reaction to light. Homatropine and cocaine was used and as he could not be removed from his bed I had to examine him in the recumbent position on the verandah of the ward by the indirect method. The fundus appeared to me very much like that of an extensive retinitis with hæmorrhages in the retina and some in the vitreous. Two days later when he could sit up he was properly examined in the dark room and his fundus revealed a true picture of commotio retinæ, traumatic œdema of the retina, concussion of the retina, or Berlin's opacity as it is also called, a very rare and interesting eye disease.

Examination of right eye.—No changes were seen in the anterior segment of the globe except a small conjunctival hæmorrhage. The optic disc was hyperæmic and the retinal blood vessels were dilated, chiefly the veins. On the outer side of the disc both above and below the macula were noted numerous greyish-white spots, more or less circular. These were irregularly disseminated in the area above the macula but seemed to coalesce to form a more or less uniform milky white cloudiness or opacity in the area below the macula. The macular region did not seem to be noticeably affected. The lower opacity was arching underneath it as it were. The retina in this region was much raised as could be seen from the blood vessels overlying it. No folds in the retina or tortuosity of the vessels, the distinguishing character of a detachment, could be seen. There were numerous hæmorrhages in the retina and a tag was seen floating in the vitreous. The brunt of the mischief was located on the outer side of the disc above and below the macula, though a few similar and isolated opaque white spots were also seen on the nasal side some distance from the disc.

The left eye.—In the left eye, that is the side on which the broken steering wheel had made a cut below the outer angle of the eye, about four such opaque white spots of exudation could be seen on the outer side some distance above the disc; except for these it was normal.

This condition was first described by Berlin in 1813 and according to him is an "œdema of the retina"; according to Leber it is "a stretching of the retina with minute laceration" (Fuchs). A severe contusion is usually the cause. The part of the retina to be affected is usually opposite to the point of impact of the blow. Experiments made to elucidate the pathology of this condition suggest that "it is an œdema of the retina brought about by transudation in consequence of the traumatic vascular paralysis of the choroidal vessels. The fluid enters the retina by diffusion," (Roemer). Collins and Mayo also state that in commotio retinæ, produced experimentally, examination of the eyes reveals the presence of an extravasation of blood between the choroid and the sclerotic, and this extravasation, causing pressure upon the delicate vascular layers of the choroid, produces a condition of ischæmia in it. We know that the outer layers of the retina derive their nutrition from the chorio-capillaries of the choroid and when these are pressed upon a serous effusion occurs in the retina, and a swelling of the outer layers takes place and the opacity develops. On the resumption of the circulation in the choroid due to the absorption of the extravasation, the opacity in the retina also begins to disappear and the *status quo* may again become established. If, however, the ischæmia of the choroid takes too long to disappear the inner elements of the retina, the rods and cones,

may also become damaged and then atrophy of the retina and only partial restoration of its function may be the eventual outcome. The epithelial cells of the retina having a greater resisting power, then proliferate and penetrate forwards into the retina and produce the pigmentation sometimes seen as the end result. The causes are direct injury, or, as it occurred here, a contre-coup, i.e., for an injury to occur at one macula, some part of the anterior half of the eyeball or the orbit opposite to it should receive the blow. In the case of a blow on the cornea the opacity in the retina would be most marked around the disc, the fovea standing out prominently near this white background. The impact and the injury need not necessarily be exactly opposite, for it is the direction of the impact that counts and determines the seat of the injury that follows, and I have no doubt that the impact of the steering wheel on the bone just below the external commissure of his left eye gave rise to the opacity at the macula in the right eye, the result of the contre-coup, as there was no external evidence of any injury whatever on the right eyeball or the eyelids or its neighbourhood.

The treatment carried out was of the ordinary nature.

Atropine in the effected eye, complete rest in bed and a bandage over both eyes was enjoined for the greater part of the day. He had leeches and inunctions of blue ointment on his temples and internally potassium iodide and mercury, supplemented with saline subconjunctival injections. The vision in the right eye improved to 6/60 on the 12th August, 1929, and the patient felt sufficiently well to start taking the jump once again in spite of being heartily advised not to do so. On the 18th August his vision in the right eye improved to 6/36 and he left the city with the circus for Nadiad. On the 28th August when he returned, the vision had improved to 6/12 in right eye and in the left eye it was 6/5. On examination it was seen that a large part of the opacity in the retina, particularly in the upper part, had disappeared, but a faint opacity was still present in the lower region with some mottling and pigmentation there. The patient turned up again on 27th September 1929, exactly two months after the injury, and it was found that the vision in the right eye had improved still further, nearly to normal, i.e., 6/6. The opacity in the retina had completely disappeared and nothing remained except some mottling of the fundus in that region.

My thanks are due to Major Candy for allowing me to treat the case.

FILARIAL PERIODICITY.

By KALI GATI BANERJEE, M.B.,
Birbhum, Bengal.

THE periodicity of the fever in infections with *Filaria bancrofti* in this country is not strictly periodic or regular. The parturition cycles

of different adult female worms may fail to be simultaneous, whilst some parturition cycles may fail to produce fever or other symptoms. Every attack does not always mean fever, nor is every filarial attack of fever followed by lymphatic manifestations. Textbooks on tropical medicine do not often draw attention to afebrile infestations with *F. bancrofti*, but such cases are not uncommon. The two following may be cited as examples:—

Case 1.—A Hindu lawyer, aged 32, who complained of a painful swelling in the left calf almost every 8th day of the lunar month. The swelling was tender to the touch and used to persist on each occasion for three or four days. There was no pyrexia at all. His grandmother is a sufferer from chronic filariasis with elephantiasis of the legs. The patient's symptoms were cured by six graduated injections of typhoid vaccine.

Case 2.—A Hindu male, aged 12, who complained of gradual swelling of the left foot with pain in the calves. The swelling grew in size at each full moon period, and when first seen, he had had three such periodical recurrences. The left inguinal glands were enlarged. There had never been any fever during the four months that the condition had persisted. No microfilariae could be found in his blood film, but the eosinophile count was as high as 7 per cent.

Case 3.—A Hindu male, aged 48, whose first attack was associated with funiculitis and orchitis. Double-sided hydrocele developed, but there was no recurrence of the funiculitis or lymphadenitis. This patient, however, suffers still from typical filarial fever off and on, and his blood films give positive findings.

With regard to the different factors associated with the disease one may mention the following:—

Heredity apparently plays no part, though sometimes four or five members of the same household may be affected, presumably on account of mosquitoes in that locality being heavily infested.

Sex.—In Birbhum the incidence in males is three times as frequent as that in females.

Age.—Adults are most commonly affected, though the primary attack seldom occurs after 30 years of age. According to Tice, workers in the tropics seldom see filariasis in patients under 14 years of age, but the writer has seen filarial orchitis in a child one month old, and orchitis and even elephantiasis of the legs have been seen in children of 12.

Season.—The disease is most prevalent in July and August during the rains; next in frequency come the months of March and April. The incidence is lowest in September and October. Low humidity is an important factor, though warmth favours the development of the larvæ in the mosquito, and warmth and moisture make the larvæ more active and favour their entry from the proboscis of the mosquito through the skin of man.

Caste, etc.—There is a lower incidence among Mahomedans and Christians in this district than amongst Hindus. Amongst the Hindus, those of the Gandhabanik class are especially susceptible, the incidence amongst them being greater in every house.

PREDISPOSING FACTORS.

Trauma.—Orchitis and funiculitis are often preceded by a slight blow in a new victim; occasionally a former sufferer has a fresh attack of localized filariasis at the site of some injury. Trauma perhaps devitalizes the part.

Overwork predisposes a previous sufferer to a fresh attack.

Intestinal stasis.—An acute attack of filariasis often follows intestinal stasis, and frequently a cathartic in a confirmed sufferer will avert an attack. Possibly the dose of cathartic may either (i) prevent the birth of microfilariae, or (ii) prevent the entrance of microfilariae from the deeper lymphatics into the peripheral circulation. Under such circumstances the difference in pressure between the thoracic duct and the internal jugular vein may not be favourable to the larvæ entering the venous circulation.

There are certain obscure points about the manifestations of filariasis which require to be answered. Thus:—

(i) Why is it that in different individuals different parts of the system, e.g., the legs, arms, genitalia, breasts, etc., are affected?

(ii) Why do some individuals show life-long manifestations in one leg, others in the scrotum, others in both, others in both legs, or in legs and arms?

(iii) Why does the local condition go on to suppuration in some cases, and not in others?

(iv) Why are some affected individuals attacked with erysipelas, septicæmia, etc., and not others?

(v) Why is the periodicity of the attacks, though definite, not entirely regular? Also, what is the connection with the lunar cycle?

(vi) Why is treatment wholly beneficial to only a few, partly beneficial to others, and not at all to the rest? Why does one form of treatment suit some, but not other, cases?

Like the malarial paroxysm, filarial fever is more or less of the nature of an anaphylactic shock. The rigors, vomiting, the high temperature, and the connection with intestinal stasis are all suggestive of colloidoclastic (protein) shock. Further, it is generally stated that if the patients rest during the day time and work at night, the periodicity is reversed, the microfilariae then invading the blood stream during the day time. But this does not explain why (i) some patients have their first attack of fever at night, others get irregular fever during the day time, still others show irregular fever during the whole 24 hours. (ii) In some microfilariae cannot be found in the blood at the time of fever, even if at night.

According to periodicity, our patients may be grouped as follows:—

(i) *Seasonal type.*—These patients get fever only at certain times of the year, chiefly during the rains from June to September, but in other instances in the winter. They are absolutely free from attacks at other seasons. During the febrile season they get frequent attacks, once a week

or twice a month, accompanied by eosinophilia almost invariably. This group also includes patients who get only one attack a year.

(ii) *Lunar type.*—This class forms the majority of our patients. These patients develop symptoms either at new moon, on the 8th or 11th day of the lunar cycle, or at full moon. There is regularly one attack in each lunar cycle. The relationship of filarial periodicity to the lunar cycle at present remains a mystery.* Perhaps at these periods the body immunity is at a low ebb, or the tissue fluids are in a condition favourable for the microfilariae to invade the peripheral circulation.

(iii) *Irregular type.*—These are the chief sufferers. The patients first have fever once a month, then some four or five attacks are followed by two or three bouts of fever during a single month. There may then be some cessation followed by most irregular febrile attacks.

(iv) *Chronic type.*—This usually follows on the irregular type of case, intervals of three or four years occurring between the attacks.

(v) *Septicæmic type.*—That filarial septicæmia does occur, and that it may prove fatal, is an admitted fact. But whether it is due to secondary streptococcal infection or to absorption of some toxin from dead microfilariae, it is difficult to say. The following are illustrative cases:—

Case 4.—A Hindu widow, aged 54, a sufferer from chronic filariasis with elephantiasis of both legs. On the 11th day of a lunar period I saw her when she was suffering from an intense attack of fever, with a temperature of 105°F. There was intense pain, with redness and swelling, in the left breast. The left axillary glands were also enlarged. Within four hours she developed coma and delirium. The urine was free from albumin and sugar. I gave a subcutaneous injection of 12 cgms. of sulfarsenol, but she succumbed within 24 hours.

Case 5.—A Hindu male, aged 48, who had had an elephantoid scrotum for many years. As was usual, one night he had fever with rigors, and intense pain, redness and swelling in the scrotum. Coma and delirium developed within a few hours of the onset of the attack, and he died within 48 hours.

Case 6.—A Hindu male, aged 24, who had suffered from filariasis for one year. There was a right-sided hydrocele with swelling and tenderness of the right inguinal glands. He used to have an attack once a month, lasting for 24 to 36 hours, the attacks beginning with chill and rigor. There were inflamed red streaks along the anterior aspect of the right thigh (inflamed lymphatic channels). The patient was conscious, but had had several stools with blood and mucus in them. The parents had no idea of the gravity of the case. The patient passed half a dozen such stools and then collapsed and died, without medical assistance having been summoned.

Case 7.—An up-country man, aged 38, brought to the Medical College Hospital with coma, generalized

[*The attention of the reader, as well as that of the author, is drawn to Col. Acton and Dr. Sundar Rao's article which appeared last year in the November number of this *Gazette*. These writers give a very satisfactory explanation of this phenomenon; it is probably a question of periodicity in giving birth to the larvæ by the adult gravid female worm, the birth of larvæ being accompanied by the ejection of a toxin which causes the fever. Many other questions raised by the writer of the present article have been dealt with in the paper referred to above.—EDITOR, I. M. G.]

lymphadenitis, and high fever. The case was suspected to be one of plague, but examination of blood films and of gland puncture films showed myriads of microfilariae. After injection of salines, etc., this patient recovered.

Post-mortem examination in two such cases of filarial septicæmia showed myriads of microfilariae in the bone marrow, spleen, liver, and the arteries of the brain.

COMPLICATIONS ALTERING THE COURSE OF FILARIAL PERIODICITY.

(i) *Sepsis*.—Secondary infection with either staphylococci or streptococci or both may occur and suppuration may take place in some cases. The temperature then becomes remittent or of a hectic type.

(ii) *Erysipelas* may set in in the affected part, and give rise to a temperature chart of a characteristic type. Curiously enough, after recovery

and persist for many days. The following is an illustrative case:—

Case 8.—A Hindu male, aged 45, a case of chronic elephantiasis of the scrotum, one day commenced to suffer from hæmochyluria. The fever lasted for only a few days, but the chyluria proved resistant to soamine, sulfarsenol, and injections of vaccine. His urine and blood both showed microfilariae. He succumbed from asthenia within two months.

(v) *Nervous manifestations*.—It is curious how nervous symptoms may occur in these patients, and with periodical regularity; probably the microfilariae in such cases invade the meningeal vessels. Headache and nervous hyperexcitability are sometimes features following after an attack of filarial fever. The following two cases illustrate this:—

Case 9.—A Hindu female, aged 26, with a history of chronic filariasis and elephantiasis of the right leg.

Marked pigmentation of the left leg with elephantiasis of both legs, the scrotum and the penis.

from such a condition, the patient often appears to have become immune to further attacks of filariasis.

(iii) *Diarrhoea* may occur; its ætiology is obscure. Possibly it is due to rupture of engorged and inflamed lymphatics in the gut, or to secondary streptococcal invasion. The prognosis is bad.

(iv) *Chyluria* may occur, and may be present together with elephantiasis of the scrotum or the legs. It may set in with the onset of the fever

One night she had a typical attack of filarial fever with pain and increased swelling of the leg. On the second day she developed diarrhoea, and after five or six stools collapsed. Stimulants were administered and she recovered, and the fever subsided within three days. She now, however, developed a staccato speech and nodding movements of the head. The tremors were involuntary, could not be checked, and occurred two or three times a second. They were also visible in the outstretched hands and in the tongue. The knee jerks were exaggerated. She was treated with calcium and parathyroid extract and Luminal for a week, and the tremors disappeared. Are these nervous manifestations

due to inflammation of the neurolymphatics of the corpus striatum, or of its vessels?

Case 10.—A Hindu male adult, a sufferer from chronic filariasis, developed stiffness and pain in the neck after one of his usual attacks of fever. There were no enlarged glands palpable in the neck, nor any other sign of local inflammation.

(vi) *Pigmentation.*—Pigmentation occurs in the chronic elephantoid masses. Perhaps it is due to destruction of the trophic nerve fibres, their nutrition being cut off by hypertrophy of the skin and blockage of the lymphatics. The

Case 11.—A Mahomedan female, a nullipara, aged 28, a widow, who had had elephantiasis of her right breast, with enlargement of the right axillary glands for some ten years. She gradually developed a hardness in the tumour of the breast, with increase in its weight and excruciating pain. On examination the mass was found to be of stony hardness, with the right axillary glands also of stony hardness, and also solid swelling of the right arm. The case was an inoperable one, and the patient died from cachexia and septic fever; a few months before death there developed a typical malignant ulcer over the affected breast.

Case 12.—A Hindu female, aged 44, multipara, had had filarial elephantiasis of the right breast since the

patient whose photograph is here shown showed marked pigmentation of the left leg, with elephantiasis of both legs, scrotum, and penis.

(vii) *Carcinoma.*—It is easy to understand how carcinoma may invade tissue involved in filarial elephantiasis, for (i) there is constant irritation of the part, and (ii) there is poverty of the lymph supply due to blockage of the lymphatics by the dead filariae or by invasion with secondary septic organisms. Probably in such cases the patient has a predisposition to carcinoma. The following two cases are illustrative:—

age of 18. She consulted no one until increasing pain and heaviness in the breast made it certain that the condition had become malignant. Examination of sections of the tissue confirmed the diagnosis of malignancy, and after amputation of the right breast and removal of the axillary glands, she is now under radium treatment.

(viii) *Filarial colic.*—This is a condition where the patient, after or during a typical attack of filarial fever, complains of extreme pain in either (i) the right or left iliac fossa, (ii) the epigastric region, (iii) the right or left kidney region, whilst there are often present vomiting, chill, and

fever. Such cases are often mistaken for ones of appendicular, gastric renal, or intestinal colic. After a few hours the pain may spontaneously disappear. The following is an illustrative case:—

Case 13.—A Hindu male, aged 30, was suddenly seized on the 11th night of the lunar cycle with intense colicky pain in the left iliac fossa and vomiting. He soon became unconscious, with pyrexia. Next morning the pain abated, but the fever lasted 72 hours. The next month he had a similar attack, with orchitis on the right side in addition. After three or four such attacks a solid œdema of the right leg developed, and the diagnosis of filariasis was confirmed by examination of the blood at night.

Case 14.—An Anglo-Indian female, aged about 48, was admitted to the gynaecological department for (i) dull pain in the left loin, often giving rise to pain of a colicky nature with vomiting; (ii) a hectic type of fever. At first sight the case was taken to be one of pelvic trouble, but vaginal examination revealed nothing abnormal. When referred to the medical side, the case

Time.	6 a.m.	9 a.m.	Mid-day.	6 p.m.	9 p.m.	Mid-night.	3 a.m.
Blood	0	0	0	1	62	50	10
Urine	7	36	43	24	26	28	34

was taken to be one of renal colic, but radiography showed nothing abnormal. Finally, one night she had high fever, and examination of the blood showed

Manson failed to find microfilariae in two cases where blood was aspirated by spleen puncture. Yet if microfilariae are not present in the deeper organs during the day time, how are we to explain their presence in such organs at post-mortem examination?

Other workers state that filarial periodicity is an expression of periodicity on the part of the gravid female *F. bancrofti* in giving birth to her larvæ. But if the microfilariae are absent from the internal viscera during the day time, then there must be an enormous daily destruction of them. Manson gives the following observations on three-hourly findings in a patient followed up for six consecutive nights and days, as to the number of microfilariae present in a blood smear $1\frac{1}{2}$ by 1 inch in size, and in the deposit from one ounce of chylous urine from a case. The actual number of microfilariae present were as follows:—

In my case No. 8 the same plan was followed, and the figures were:—

Time.	6 p.m.	Mid-day.	6 a.m.	Mid-night.
Blood	1	0	0	48
Urine	18	50	18	0

microfilariae present. A course of intravenous injections of soamin relieved her of all symptoms. This colic may be due to inflammation of the perirenal lymphatics.

The other forms of colicky pains are due to invasions of the intestinal lymphatics plus stasis, or in some cases to inflammation of the spermatic lymphatics following the course of the spermatic vessels of the cord.

PATHOGENESIS.

Filarial periodicity is evidently produced in one of two ways. Firstly there may be a fixed population of microfilariae within the body, which shelter in the internal viscera during the day time, and only enter the peripheral circulation at night. According to Manson "The deeper parts where they retire are the larger blood vessels, particularly arteries; they mostly lodge in the blood vessels of the lungs." If this is true, at post-mortem examination one would expect to find many more microfilariae in the lungs of patients who died during the day time than in those who die at night; but this is not the case.

The other possibility is lodgement of the microfilariae in the larger blood vessels during the day time. It is difficult however to imagine how this occurs, and Fulleborn has found microfilariae in myriads in the circulating blood within the heart at post-mortem examination.

Fulleborn holds that, together with the contraction of the superficial blood capillaries at night, the larvæ take up a slightly bent attitude, and are thus retained during the day time in the deeper capillaries and pre-capillaries, but that in shed blood this bent attitude is not shown.

The chart shows that the urinary periodicity is entirely different from the blood periodicity.

This shows that filarial embryos are constantly passing to the lymph stream, and the figures in the table do not give their true incidence in the lymph. Manson-Bahr observes that multitudes of microfilariae die or are cut off from the main blood stream by inflammatory blockage. He also found that they did not live at body temperature in citrated blood for more than 12 hours, but in citrated blood at room temperature they survived for three days. Now, if microfilariae are short-lived, how are they disposed of? There are two possibilities. (i) Meyer in China reports that death and dissolution of the microfilariae occurs in the plasma, and is more rapid in the morning than in the evening blood. Perhaps, just as there is a lysozyme in tears which has a bactericidal property, so perhaps there exists in the blood some substance lethal to microfilariae. (ii) Rodenwaldt implicates the renal medulla as a veritable burying ground of microfilariae. Anderson found dead microfilariae in process of dissolution in the liver, spleen, and lymph glands.

To sum up, the microfilariae perish rapidly within the blood stream, whilst the filarial periodicity is the result of cyclical parturition, and is adapted to the habits of the transmitting mosquito host. We are still, however, too much in the dark with regard to the pathogenesis and mechanism of filarial periodicity. The mighty elephant of Truth stands unexplored, and we, like the blind fellows in the fable, feel its legs

and declare them to be mighty pillars, or its ears and take them to be mighty fans, each thinking alike that he is the nearest to the truth.

SOME OBSERVATIONS ON AN UNUSUAL EPIDEMIC OF MALARIA IN THE CITY OF LUCKNOW (APRIL—SEPTEMBER 1929).*

By A. C. BANERJEA, M.B., B.S.,

Assistant Malariologist, United Provinces.

INTRODUCTION.

THE city, which is the largest in the United Provinces, is located mainly on the south bank of the Gomti river. The Gomti river forms a very definite landmark, as well as one of the most important physical features of the city from a malarial point of view. The city is divided for purposes of municipal administration into eight wards, seven being on the south and one on the north of the river.

Another landmark of importance is the bed of the obsolete Ghazi-Uddin Haider "nala" which enters the municipal limits west of the Aishbagh Railway Junction and continues close to the southern boundary till it meets the Gomti river. Part of this disused "nala" was cunetted in 1928 and the work is still proceeding.

The population of the city, according to the census of 1921, was 2,17,167. The crude death rate for 1928 was 45.65 and the mean death rate for the previous five years (1923—27) was 39.76 per 1,000 of population. The birth rate for the year 1928 was 51.89, and the mean birth rate for the previous five years (1923—27) was 47.47 per 1,000 of population.

There is no evidence to show that Lucknow in the past was ever visited by an epidemic of malaria, and although the town was not free from malaria, the incidence as judged by spleen rates

* Being a paper read at the Medical and Veterinary Section of the Indian Science Congress, Allahabad, January, 1930.

was only 3.1 per cent. in 1913. Since then, owing to various anti-malarial schemes carried out, this rate has further fallen to 1.4 per cent. (1923).

PRESENT OUTBREAK.

The present outbreak was coeval with the usual benign tertian rise in March and April. The first indication given was a sudden increase in the hospital attendances under fevers and this was followed by an unprecedented rise in the mortality from fevers. The high death rate in the benign malaria season when epidemics of malaria are unknown and in the absence of any marked increase in the carrier anophelines until May, led us to suspect that the basis of the high death rate must be a fever of very toxic clinical manifestations. There is some evidence to suggest that the early rise in the benign season was complicated by a malaria-like undifferentiated fever associated with enlargement of the liver and spleen and the presence of jaundice.

In order, therefore, to determine the true nature and extent of the disease causing this high death rate, a very systematic and careful investigation was undertaken and the following are in brief the findings:—

(1) EXAMINATION OF HOSPITAL CASES.

An examination of the local dispensary returns shows that attendance under fevers was higher from January 1929 onwards as compared to the average of the previous four years. This rise was, however, further accentuated from April right up to September with the peak in May.

It is to be noted, however, that the absolute increase is most marked in August, but this is more apparent than real when compared to the normal of previous years. Thus the rise in the rate per 1,000 of population in August 1929 is 5.1 times the average of the previous four years for August, while that of May 1929 is as much as 6.1 times the average for May.

Fever attendance in the city hospitals is as follows:—

Month.	4 years' average of fevers (1925—28).	Rate per 1,000 of population.	1929.	Rate per 1,000 of population.	Number of times greater than the average of pre- vious 4 years.
January ..	1,001	4.61	2,326	10.71	2.3
February ..	1,036	4.77	1,823	8.39	1.7
March ..	1,691	7.79	3,377	15.55	2.0
April ..	1,945	8.96	8,761	40.34	4.6
May ..	1,948	8.97	11,958	55.06	6.1
June ..	1,607	7.40	2,594	34.97	4.7
July ..	1,964	9.04	10,705	49.29	5.4
August ..	3,152	14.51	17,364	79.96	5.1
September ..	3,283	15.12	13,320	61.33	4.1

The following comparative statement shows the deaths under fevers month by month:—

the liver. All these 144 had a history of enlarged spleen. The average duration of fever varied from 2 to 10 days before death.

MORTALITY.					
Month.	Deaths from fevers—4 years' average (1925—28).	Rate per 1,000 of population.	Deaths from fevers (1929).	Rate per 1,000 of population.	Number of times greater than the average of previous 4 years.
January ..	61	0.28	143	0.66	2.3
February ..	61	0.28	184	0.85	3.0
March ..	109	0.50	339	1.56	3.1
April ..	185	0.85	607	2.79	3.2
May ..	235	1.08	1,315	6.05	5.6
June ..	246	1.13	742	3.42	3.0
July ..	160	0.73	312	1.44	1.9
August ..	169	0.77	782	3.60	4.6
September ..	167	0.76	800	3.68	4.8

From the statement given above it will be seen that deaths from fevers have been appreciably high since the beginning of the year. In the earlier months of the year as smallpox, measles and plague were prevalent in the city it is possible that some of these have been shown under fevers, but from May onwards in the absence of any other epidemic disease, the deaths under fevers can be taken to represent the true fever mortality and this, as will be seen from the table given, has been as high as 5.6 times the average figures for 4 years in the months of May and 4.8 times those of September.

It will also be seen that the absolute increase in the number of deaths is more marked in the month of May, as there were as many as 1,315 deaths, while in the month of September there were only 800 deaths. A comparison of the mortality figures with the dispensary records of fever attendance shows that the two do not follow one another very closely. Roughly speaking the increase of mortality followed the increase in sickness but the case fatality rate varied from month to month.

It is very difficult to calculate a correct case fatality rate as all the cases in the city did not come to the hospitals, nor were all the reported deaths verified by qualified agencies.

VERIFICATION OF DEATHS.

Three hundred of the deaths under fevers were verified by house-to-house inspection. These deaths were taken at random in the various wards of the city. Particulars regarding each death were recorded upon a slip and whenever a diagnosis by a qualified medical man was available, the particulars were obtained from him and the results of various sortings were noted.

Of the 300 deaths investigated 144 could be definitely attributed to malaria. Out of these, 39 had very marked symptoms of abdominal pain with dysenteric stools particularly in the period immediately preceding death, and 7 had very pronounced jaundice, and enlargement of

The mortality (January to August 1929) according to age groups is as follows:—

Still births	334	(Previous 4 years' average—258 for the same period.)
Children under one year ..	995	
1 to 5 years ..	1,007	
5 to 10 years ..	250	
10 to 15 years ..	159	
15 to 20 years ..	163	
20 to 30 years ..	278	
30 to 40 years ..	270	
40 to 50 years ..	281	
50 to 60 years ..	335	
60 and upwards ..	686	
	<u>4,758</u>	

Of the 4,758 deaths at Lucknow during the months of January to August 1929, 2,336 or 49.1 per cent. deaths were therefore in children under 5 years of age, as against 2,422 or 50.9 per cent. for all other ages; 1,021 or 21.4 per cent. deaths were in persons 50 years and over.

Associated with the increased mortality there was also a definite increase in the reported still births. During the period January to August 1929, there were 334 still births against 258 still births, the average of the corresponding period of preceding 4 years (1925—28).

METEOROLOGICAL.

(1) The average range of temperature shows a considerable variation from season to season. In the cold weather the minimum temperature drops down to about 34°F. and in the summer months the temperature in the shade is as high as 116°F.

(2) The average rainfall per annum varies from 17 inches to 62 inches over a period of 30 years (average approximate 38 inches). It is not proposed to discuss at length the meteorological data, as since the flood of 1924, the variations in temperature and humidity have been within normal limits and not sufficient to affect the incidence of malaria unduly in the succeeding years. There are, however, two important

facts:—(i) the year preceding the present outbreak was one of drought, and (ii) this year (1929) there was an excessive rainfall in the period between the middle of July and the middle of August, the excess being about 15 inches above the normal of the past three years for the same period. The rise in the fever incidence during August and September is partly attributable to the heavy rainfall in July and partly to relapse of infection contracted in the months of April and May.

SPLEEN RATE.

The splenic rate observed in different areas of Lucknow in the month of August 1929 is as noted below:—

of benign tertian infection; 225 or 24 per cent. malignant tertian, 7 or 0.8 per cent. quartan and 41 or 4.2 per cent. were mixed infections (benign tertian and malignant tertian parasites). Four per cent. of the slides showed sexual forms—(crescents or benign tertian gametocytes).

The morphology of the parasites did not differ from any of the recognised forms. The intensity of infection was in most cases very severe: roughly 80 to 100 parasites per 200 red blood cells in about 50 per cent. of both the malignant tertian and benign tertian slides. This intensity of infection by benign tertian parasites has never before been seen in this province during any survey.

Name of ward.	Location of ward, central or on outskirts of city.	Number of children examined.	Number of children found with enlarged spleen.	Percentage with enlarged spleen.
1. Hazratganj ..	Both ..	328	21	6.4%
2. Hasanganj ..	Mostly outskirts ..	155	15	9.7%
3. Ganeshganj ..	Purely central ..	495	25	5.0%
4. Wazirganj ..	Mostly central ..	696	127	18.3%
5. Yahyaganj ..	Purely central ..	220	108	49.0%
6. Chowk ..	do. ..	183	57	31.1%
7. Saadatganj ..	Partly central ..	111	13	11.7%
8. Daulatganj ..	Outskirts ..	242	43	17.7%
TOTAL ..		2,430	409	16.8%

Of the 2,430 children examined 409 or 16.8 per cent. showed enlarged spleens varying in size from one to three finger-breadths. Of the 8 wards in the municipality, Yahyaganj and Chowk wards showed spleen rates as high as 49 per cent. and 31 per cent. respectively. The spleen rate figures in 1913 and in 1923 were never more than 3.5 per cent. in any of the wards of the city.

From the above figures it will be seen that the spleen rate has been very high, more especially in the wards centrally situated, with the exception of Ganeshganj ward. This fact when considered with other findings brings out certain very remarkable features of the epidemic and has an important bearing on the epidemiology of the disease. It will be discussed later on in the report.

BLOOD EXAMINATION.

During the period under review 1,519 blood slides were examined. The blood slides were taken at random from the cases attending for fevers in the various hospitals of the city. Of the 1,519 slides examined 941 or 61.9 per cent. were found infected with malarial parasites. Of these positive slides 668 or 71 per cent. were

ENDEMIC INDEX.

In order to determine the percentage of children harbouring malarial parasites, blood slides were taken from 350 children in the various schools of the city. Of the 350 slides examined 55 or 16 per cent. were found infected with malarial parasites and 3 per cent. of the positives showed crescents and *P. vivax* gametocytes.

BREEDING GROUNDS OF THE ANOPHELINE MOSQUITOES.

The principal active breeding grounds in Lucknow have been as under:—

1. Stagnant pools in the bed of the Ghazi-Uddin Haider "nala" which passes through the city.
2. Some 25 sewer outfalls, or storm water channels on both banks of the river Gomti and the edges of the river itself.
3. Irrigation tanks in the public gardens.
4. Tanks in private gardens.
5. La Martinière Lake.

6. Temporary collections of rain water in low lying areas of the city.

7. Wells.

All these breeding grounds are systematically and regularly fished for anopheline larvæ each year and as soon as it is discovered that the breeding of mosquitoes has started extensive oiling or Paris-greening is commenced. In April and May 1929 there was an abnormal amount of anopheline breeding in the river owing to the fact that the sluice gates, which are let down once a week as a routine in order to flush out the river, were out of order. Since May there has been practically no breeding of anopheles in the river, as the gates were repaired.

It appeared that the earlier part of the epidemic, or the abnormally higher seasonal incidence of the normal benign tertian rise, was due to breeding in the edges of the Gomti river. During the rains it was found that "kachha kalas" were breeding *A. culicifacies*. This finding was peculiar and was probably caused by the fact that the rains were exceptionally heavy and backwaters in nalas previously too foul to breed carrier anophelines became active breeding places. As the season progressed, it was found that the cases as well as deaths were becoming more numerous in the Chowk, Saadatganj and Yahyaganj wards and in the central portion of the town. These wards are practically free from any of the known active mosquito breeding grounds and although

There was always great difficulty in finding larvæ in wells. In the month of August, however, after a break in the rains, the wells became an active source of larvæ of *A. stephensi*. Until this date, very active well breeding had never before been recorded in Lucknow, although the 1913 report by Major Graham had laid down recommendations for these wells and had given a forecast that sooner or later an epidemic might result unless the wells were dealt with. In this epidemic, public wells were not to any extent of the same importance as domestic and private wells. Considerable difficulty was experienced in obtaining access to these latter wells owing to the strict purdah system prevailing in the city, and as there are 5,167 recorded wells (and many unrecorded private wells) the problem was of extreme difficulty. The epidemic would not have occurred if the recommendations laid down by Major Graham in 1913 had been carried out (*vide* appendix).

In this connection it is also interesting to note that of the 5,167 wells distributed all over the city there are as many as 1,392 wells in the Yahyaganj Ward. This ward gave a spleen rate of 49 per cent. and also showed the highest mortality from fever.

ANOPHELINE MOSQUITOES.

The following species of mosquitoes were classified and are shown in order of their prevalence—(April to September):—

Months.	Number of adult catch.	<i>A. subpictus</i> . (1)	<i>A. fuliginosus</i> . (2)	<i>A. culicifacies</i> . (3)	<i>A. stephensi</i> . (4)	REMARKS.
January ..	(207)	94%	4%	2%	0	(1) Non-carrier.
February ..	(189)	93%	3%	4%	0	(2) Doubtful carrier.
March ..	(314)	90%	6%	4%	0	(3) Efficient carrier of malarial parasites in nature.
April ..	(405)	91%	5%	4%	0	(4) Do.
May ..	(699)	86%	9%	5%	0	
June ..	(486)	89%	7%	4%	0	
July ..	(290)	92%	4%	1%	3%	
August ..	(704)	80%	5%	3%	12%	
September ..	(590)	85%	5%	2%	8%	

the wells were known to be potential breeding places, practically no breeding was found to be occurring in these before the month of August.

INFECTION IN MOSQUITOES.

The following table shows the numbers of mosquitoes dissected:—

	Number dissected.	Number found infected.	Percentage infected.	Mid gut.	Salivary glands.
<i>A. subpictus</i> ..	89	Nil	Nil	Nil	Nil
<i>A. fuliginosus</i> ..	78	Nil	Nil	Nil	Nil
<i>A. culicifacies</i> ..	60	Nil	Nil	Nil	5
<i>A. stephensi</i> ...	75	7	9.3	7	

From the above it will be seen that *A. stephensi* was the only species that could be incriminated in nature.

CONCLUSIONS.

The study of the present outbreak of fever in Lucknow has brought out the following important features:—

1. That a considerable proportion of the fever rise (April to September) was attributable to malaria.
2. That the epidemic of malaria broke out in the so-called "benign season"—the late spring. The months and the year preceding the outbreak were exceptionally dry.
3. That the epidemic of malaria was associated predominantly with benign tertian infections. The total percentage of infection found in cases was 61.9 per cent. Benign tertian infection formed two-thirds of these infections, and malignant tertian, quartan and mixed infections accounted for the remaining one-third.
4. That the intensity of infection was very severe. In about 50 per cent. of slides examined there were roughly 80 to 100 parasites per 200 red blood cells. In the other 50 per cent. the infection was also moderately severe.
5. That there were many cases of fatal abdominal malaria, typhoid remittent, and a few cerebral cases. Owing to the fact that most of the deaths took place outside the hospital and blood slides and post-mortems could not be obtained in any circumstances, the proportion of benign tertian and malignant tertian infections in fatal cases could not be estimated.
6. That the cases and deaths were mostly in the congested localities in the centre of the town, while the "mohallas" on the outskirts were not so badly affected.
7. That the wells (the potential breeding grounds) became most *prolific sources* of *A. stephensi* which was also incriminated infected in nature. That the Yahyaganj ward, which has the largest number of wells in the city suffered the most.

APPENDIX.

Recommendations by Major J. D. Graham, I.M.S., for the prevention of Malaria in Lucknow, (1913).

"It may be argued, and with reason, that as malaria is so mild in Lucknow city, no drastic measures are at present indicated. As, however, we have now strong reasons for believing that epidemic malaria originates under certain very favourable but unknown circumstances from existing endemic malaria, it is advisable to attempt to control, if not to eradicate, the existing sources of the disease. The problem is made easier by the fact that these have been shown to be comparatively circumscribed. Moreover, a very similar problem, thought on a very much larger scale, is now being solved in Bombay city where, as has been shown, certain

wards were very definitely affected by malaria carried by the *stephensi* mosquito which bred mainly in the wells, while other wards escaped almost entirely. We have to deal in Lucknow then with this condition on a small scale and with its possibilities as well....."

A Mirror of Hospital Practice.

A CASE OF ALKAPTONURIA.*

By H. K. SINHA, M.B., B.S.,

Department of Physiology, King George's Medical College, Lucknow.

ALKAPTONURIA is an inborn error of metabolism in which the body is unable to deal with the constituents of the protein molecule called tryptophane. Its existence has been noted clinically for some centuries in Europe and less than 20 cases have been recorded so far.

Knowledge of the nature of the condition commenced in 1858 when Bodeker detected in the urine of a glycosuric patient a second reducing substance (not sugar), and on account of its behaviour to alkalis named it alkapton, a word derived from alkali and *ἀπτερυγ*. Further investigations were carried by other investigators following Bodeker. Clinically the existence of the disease can be traced as far back as 1584. This case has been recorded as follows:—

S. M., aged 35, Mohammedan, male, married.

Occupation, cultivator. He was not a vegetarian. Living in Azamgarh District.

Complains of—

- (1) Urine getting black after some time, since childhood.
- (2) Painful micturition in hot weather, since childhood.
- (3) Blue deposits in external ear, palms and fingers, for 20 years.
- (4) Pain in the joints and tender spots and the body, for 5 years.
- (5) Swellings in the tendons, for 4 years.

Family History.—(Paternal family). None suffered from such disease. Father is alive and healthy.

(Maternal family.) No such complaint in any person in the family.

* Sent by Dr. C. S. D. Misra, M.B., B.S. (Jaunpur) to the Department of Physiology.

Brothers and sisters. The patient had two twin sisters 4 years younger than himself. One of them had this sort of urinary disturbance, and died at the age of 17 from cough, fever and wasting. The younger had normal urine and died at 2 from cough, etc.

Habits.—Chews betel nut and tobacco.

History of past illnesses and present.—The patient says that his parents noticed that the wet clothes of their child used to turn dark after some time, and the washerman could not remove the stains. They got him and the mother treated by local *Vaidas* and *Hakeems* for several years without any result. Then they decided that the condition would not harm him and the treatment was given up.

At the age of 15 he noticed faint bluish deposits very deep under the skin of the palms and index fingers of both hands. They went on increasing till the present condition was reached.

At the age of 25 he went to Rangoon and was working there as a tea-seller and baker. About 6 years ago when he was at Rangoon he had an attack of fever which lasted for more than two weeks during which time he was not allowed to take any solid food. After his recovery one day while climbing stairs he felt something giving way in his left groin and there was pain. Since then he very often feels such sort of sensation and pain at various parts of his body in nearly all his joints and has got tender spots in his muscles.

About 4 years ago while running he felt a sharp pain in his left tendo achillis and the part became weak and swollen. It subsided after a month and a nodular swelling remained and the power of the part returned gradually. The same story was repeated with the right leg as well, about a year ago. Gives no venereal history and has never suffered from dysentery. No history of chronic arsenical poisoning or carbolic acid, either by the way of treatment or for other purposes.

Physical examination.—General. The patient is a young man of average intelligence and strong build. There are blue deposits in the cartilages of the pinna and on the lateral surfaces of the index fingers and thenar and hypothenar eminences. The epidermis is peeling off over the deposits of the fingers. The deposits are bilateral. He has got solid swellings over both tendo achillis. Epitrochlear glands are not enlarged.

Sites of pain. (On pressure and while walking.)

(a) $\frac{1}{2}$ inch below the lateral malleoli (bilaterally).

(b) Lateral tuberosity of femur (bilaterally).

(c) Insertion of patellar tendon (bilaterally).

(d) Insertion of tendo achillis (bilaterally).

(e) Right lateral side of biceps femoris (muscular).

(f) Right posterior calf muscles.

(g) Right anterior inferior iliac spine.

(h) At the right side of the spinal region in the back just below the 12th rib. On pressure the pain shoots down the right buttocks up to the gluteal fold laterally.

(i) Medial condyle, right humerus.

Alimentary, circulatory, and respiratory systems are normal.

Reflexes and jerks are normal. Mentality seems to be slow.

Tender spots are present on his right tibial tuberosity.

Urine.—Reaction—Acid (to litmus, but was not sensitive to tripoclin).

The urine remained acid for 72 hours (litmus).

Colour—Deep brown.

Sp. Gravity—1032.

Deposits—None.

The urine becomes dark on exposure to the atmosphere after some time.

The black deposit on exposure to air was amorphous microscopically.

Sugar—Nil.

Albumin—Nil.

Bile—Nil.

With 20 per cent. KOH solution on heating it becomes dark.

The darkening of the urine interfered with the accuracy of observation of the reduction with Fehling.

On adding ferric chloride solution a bluish violet colour appears which fades quickly.

Shows presence of homogentistic acid in the urine.

My thanks are due to Dr. Burrage, Head of the Department of Physiology, for permission to publish this article.

MARCH.

ANTI-RABIC POLICY IN INDIA.

A SUBJECT which came up for discussion at the annual Conference of Medical Research Workers in December, 1929, in Calcutta, and which is of considerable interest to our readers is the future of anti-rabic policy in India.

Of recent years considerable work has been carried out at certain Pasteur Institutes in Central Europe on the use of an anti-rabic vaccine in which the virus has been attenuated by exposure to ether; this work culminating in the paper published by Alivisatos in 1922. The attention of workers in India having been drawn to this method, a very exhaustive trial of the method was carried out by Lieut.-Col. J. Cunningham, C.I.E., I.M.S., then Director of the Pasteur Institute, Kasauli, and his colleagues; the results being published in the *Indian Journal of Medical Research* from 1926 to 1928. This work may be summarised as follows:—

In their first paper Cunningham, Nicholas, and Lahiri (1926) found that death or very marked attenuation of the Kasauli fixed virus followed immersion of infected brains for periods of more than 36 hours in ether. After 84 hours' immersion the virus appeared to be non-viable in all cases, and the Kasauli virus appeared to be less resistant to ether than the viruses used by Remlinger (1919) and Alivisatos (1922). The virus in infected spinal cords was killed by 7 hours' exposure to ether vapour, and ether vapour appeared to have as marked an effect as immersion in liquid ether.

In their second paper, Cunningham, Nicholas and Lahiri (1927) studied the action of ether on street virus. This was found to be considerably more resistant than the Indian fixed virus, positive evidence of viability of the virus being found in the central portion of brains immersed in ether up to 72 hours. The action of ether vapour on street virus was less uniform and less rapid than its action on fixed virus. Results in general with Indian street virus corresponded to those reported by European observers. In their third paper, Cunningham, Nicholas and Lahiri (1928) report that living virus was found in spinal cords, infected with street virus, and immersed for periods up to 84 hours, but not in cords exposed to ether for 96 hours. In the case of exposure to ether vapour these periods have to be extended to 120 and 144 hours respectively. The virus in spinal cords is as resistant to the action of ether as is the virus in brain tissue. Later Cunningham, Nicholas and Lahiri (1928a) studied the fixed virus of the Pasteur Institute of Paris,

and found it considerably more resistant than the Indian fixed virus strain. Living virus was found in infected brains immersed for 144 hours, but not in brains immersed for 168 hours. In infected spinal cords the virus was found to be alive in the inner parts of the cords after 96 hours' immersion.

A new Indian fixed virus was now elaborated (Cunningham, Nicholas and Lahiri, 1928 b). This was found to conform closely in incubation period and time to death with the original Kasauli fixed virus first used in India. The virus remained alive in the interior of brains exposed for 84 hours to ether, and even possibly in brains exposed for 96 hours.

It becomes clear from this series of experiments that different strains of the rabies virus, both street and fixed virus strains, differ very considerably in their resistance to ether; that no definite period can be laid down which will be universally applicable; and that each strain of virus must be carefully tested before use.

A further study of the subject was next undertaken by Gloster, Beer, Nambiar and Sastry (1929). The authors conclude that carbolized vaccine in doses proportionate to those used for human beings confers considerable protection to guinea-pigs against subsequent infection with rabies; but that guinea-pigs and rabbits immunized with etherized fixed virus by Alivisatos' method show a higher degree of immunity than is obtainable by immunization with carbolized fixed virus, even when the latter is given in the same quantity for weight as the etherized fixed virus.

Alivisatos' method was next tested in India on man at the Kasauli Institute, and an abstract from Colonel Cunningham's report was read at the Research Workers' Conference. He reported that, although treatment with etherized vaccines did not abolish the mortality from hydrophobia among the treated, yet it brought about a very considerable reduction in the total and corrected mortality in the severest type of cases (Class IV, i.e., deep and uncauterised bites on bare skin). The most marked improvement was recorded in the face type of cases; the least in multiple bites involving both the face and other situations. He quotes the following figures for such cases:—

Total mortality rate, Alivisatos' method	4.88
" " " Hempt's method (use of two etherized vaccines of different strengths)	6.35
" " " Carbolyzed vaccine (1926, total brain substance up to 0.7 gm.)	8.62

Further, with Hempt's method, the period of treatment can be reduced from the normal 14 days to 6 days, without affecting its success. The improvement may be due to one or other of the four following factors:—

- (a) the use of living attenuated virus in the etherized vaccine;

- (b) the increased dose of brain substance;
- (c) the preliminary treatment of the brain substance with ether;
- (d) the use of massive doses at the beginning of treatment, followed by a gradual reduction until comparatively small doses are used;

and the influence of each of these factors has to be separately studied. Experiments on monkeys indicated that Alivisatos' method was superior to either Hempt's or to the use of carbolized vaccine, and that the antigenic value of the Paris fixed virus was greater than that of the Indian fixed virus.

Colonel Cunningham and Major Malone's final report, entitled "An investigation into the comparative values of carbolized vaccine and the etherized vaccines of Alivisatos and Hempt in anti-rabic treatment" was next circulated to all Directors of Pasteur Institutes in India for opinion and criticism. Whilst there was general agreement that results with Alivisatos' method might be better than with the existing carbolized vaccine, yet a general opinion was expressed that the use of a living, though etherized, vaccine might not be safe. Neuro-paralytic accidents are more frequent when a living vaccine is used. The better results with Alivisatos' method may simply be due to the fact that with it much larger doses of brain substance are given than in the present-day use of carbolized vaccine in India. A carbolized vaccine prepared from the Paris fixed virus might give as good results as Alivisatos' technique, whilst finally it was pointed out that Hempt has now abandoned the use of living virus, and uses a carbolized etherized vaccine. At the Pasteur Institute of Bengal, Captain E. C. R. Fox introduced the use of sheep's instead of rabbits' brains in 1926—in the first instance as a measure of economy, as a sheep's brain provides about six times as much vaccine as a rabbit's does. The results have been surprisingly and gratifyingly successful. After sheep's brain was introduced, the mortality in Class IV cases was as follows:—

1927. Class IV cases treated 954; mortality 2.83 per cent.

1928. Class IV cases treated 1,168; mortality 1.96 per cent.

as compared with Cunningham's figure of 4.88 per cent. in 819 Class IV cases treated at Kasauli by Alivisatos' method. The Calcutta 1928 cases indeed show more than 140 per cent. improvement over the Kasauli ones with the latter method, and appear to constitute the clearest and most unbiased evidence hitherto available in the literature as to the real value of anti-rabic vaccination.

This being the position when the all-India Medical Research Workers' Conference met in December last, the matter was referred at that meeting to a special committee, consisting of present and past Directors of Pasteur Institutes in India. The Committee's report was as follows:—

"1. A successful anti-rabic policy should be based on the following considerations:—

- (a) All persons at risk should have the opportunity of receiving anti-rabic treatment.
- (b) All persons at risk should receive treatment with the least possible delay.
- (c) All persons at risk should receive treatment adequate to the degree of risk involved.

2. To meet the above requirements the Committee put forward the following recommendations:—

- (a) In accordance with local requirements, decentralisation of treatment to subsidiary centres situated in convenient areas and in charge of an officer trained in anti-rabic work should be introduced.
- (b) The course of treatment used should be adjusted to the estimated degree of risk at the discretion of the Directors of Pasteur Institutes, and the same principles should be adopted at subsidiary centres where decentralisation is the policy.

- (c) On a consideration of the 'Report on the results of the Investigations into the Comparative Value of Carbolized and Etherized Vaccines in Anti-rabic Treatment carried out at Kasauli,' the Committee is not prepared to recommend any change in the type of vaccine at present, but considers that the results are in favour of the use of higher dosage of fixed virus and recommends that higher dosage than at present used be given where indicated.

The Committee does not feel itself in a position to bind Directors of Institutes to any fixed scheme of dosage, but considers that the experience in Kasauli of the safety and efficiency of higher dosage permits of its extended use within the limits so far tested.

- (d) More evidence should be collected as to the advisability of shortening the course of treatment in cases of minor degrees of risk, and Institutes should collect evidence on this point.

- (e) The collection of anti-rabic statistics should remain a function of the Provincial Institutes as at present regular returns of cases are being forwarded from the treatment centres. The same statistical card should be used for all Institutes in India and Burma and the sorting and tabulation should be carried out mechanically at one centre for all. A minimum of 80 per cent. of six-monthly health returns should be aimed at.

- (f) Adequate instruction of all officers in charge of treatment centres in anti-rabic work, particularly in the assessment of the degree of risk, the observation and care of patients undergoing anti-rabic

treatment, and the preparation of anti-rabic returns, are necessary.

- (g) Continued research on anti-rabic vaccine is required, not only in regard to type of vaccine (e.g., carbolized, etherized, formalinized), but also with regard to virus strains, their antigenic value, their maintenance, and the influence of the species of passage animal.
- (h) The method of disinfection of wounds, including the use of radiation, require further investigation."

It will be seen from the above summary that present-day anti-rabic policy in India is based on sound lines, but that further investigations are called for. The risks associated with the use of a living virus in Alivisatos' method appear to militate against its general introduction in India, whilst such an etherized vaccine could not be made available for general issue, as is the case with the present carbolized vaccine. The use of sheep's brains instead of rabbits' has proved very successful, both from the point of view of efficacy and economy. What seems to be most urgently called for, however, is an investigation of the antigenic value of different virus strains in India.

SPECIAL ARTICLES.

OCCUPATIONAL THERAPY.

By O. A. R. BERKELEY HILL, M.D. (Oxon.),
LIEUTENANT-COLONEL, I.M.S.,

Superintendent, European Mental Hospital, Ranchi.

No one who has any knowledge of hospitals in the United States of America could deny that

the utilization of occupation as an adjunct to other means of therapy has reached a point of development far in advance of that attained in any other country. Although occupational therapy had been in existence in the United States for one hundred and fifty years prior to the outbreak of the Great War, there is little doubt that one of the effects of that vast catastrophe was to stimulate interest in occupational therapy to a degree hitherto unknown, so that to-day no one in America regards occupational therapy as a fanciful theory of one or two eccentric medical men.

While occupational therapy has proved so far a claim to the best results with tuberculous, orthopedic and mental patients, its application to ordinary medical and surgical cases has been often highly beneficial.

Occupational therapy has had a number of synonyms, such as ergotherapy, work cure, moral treatment and diversional therapy; terms which are not free from objection because they place too much emphasis upon a single phase of a broad range of possible treatment.

In a discussion of occupational therapy for tuberculous patients for whom this type of treatment has reached the greatest degree of exactness of application, Dr. H. A. Pattison defines occupational therapy as "any activity, mental or physical, definitely prescribed and guided for the distinct purpose of contributing to and hastening recovery from injury or disease."

To all too many, occupational therapy signifies craft work and nothing more. This is unfortunate as craft work is merely one form of occupational therapy. A great variety of the activities of normal life, amusements, study, and occupations of various kinds, have been, and are being used under direction to promote recovery from physical or mental disability. When so used they are occupations, or occupational treatment.

As Dr. W. R. Dunton observes in his very useful little book, *Prescribing Occupational Therapy*, "occupational therapy, like much other human knowledge, depends for its advancement upon psychology." Unfortunately psychology has not yet determined with sufficient accuracy the physical and mental effects of the emotions upon the individual. While Cannon has produced a classic in his study of the physical effect of certain emotions, no one, so far, has been able to give an account of the converse. Nevertheless, empirical experience teaches us that if we can give a sick man an interest outside himself we shall make him more contented and happy and thereby aid in his recovery. Even with that class of patient who enjoys his invalidism or does not want to get well, it is possible, by a graded use of physical exercises, recreations and occupations to induce in him a better adjustment to life.

In circumstances such as these it is beyond dispute that every doctor should know something of the principles governing the application of

occupational therapy in order to be able to prescribe it in an appropriate manner. In administering occupational therapy the physician should bear in mind the following points: (1) In applying occupational therapy, the treatment should be prescribed and administered under constant medical advice and supervision, and correlated with other treatment of the patient. (2) System and precision are usually as important as in other forms of treatment. (Dosage should be exact. The object to be attained should be kept in mind and treatment should not degenerate into mere diversion.) (3) The treatment should, in each case, be specifically directed to the needs of the individual patient. (4) As the patient's strength and capability increase, the type and extent of the occupation should be regulated and graded accordingly. (5) The only reliable measurement of the success of the treatment is the effect on the patient. (6) The occupation selected should be within the patient's estimated interests and capacity. (7) Though some patients do best alone, employment in groups is usually advisable, whenever possible, because it provides exercise in social adaptation and the stimulating influence of example and comment. (8) Inferior workmanship, or employment in an occupation which would be trivial for the healthy may be attended occasionally with the greatest benefit to the sick or injured; but standards entirely worthy of a normal person must, as a rule, be maintained for proper mental stimulation. (9) The production of a well made, useful, and attractive article, or the accomplishment of a useful task, requires healthy exercise of mind and body, gives the greatest satisfaction, and thus produces the most beneficial effects. (10) Novelty, variety, individuality, and utility of the product enhances the value of an occupation as a treatment measure. (11) Quality, quantity, and saleability of the products may, at times, prove beneficial by satisfying and stimulating the patient, but should never be permitted to obscure the main purpose of the treatment which, of course, is therapeutic.

We may now pass from the general consideration of occupational therapy as a therapeutic measure to a consideration of some of its special applications.

For Tuberculous Patients.

Occupational therapy for the tuberculous has been the subject of considerable research in America and the method of its application has been fairly well standardized. In treating this group of patients we have the advantage of objective signs in determining the dosage. A rise of temperature is an almost sure indication that the individual has done too much, but occupation should stop before this point is reached. It is essential, therefore, to watch patients carefully for early signs of fatigue. Although rest is of prime importance in the treatment of tuberculosis, too much emphasis may fall on muscular rest and

too little on mental rest. It is quite impossible for some temperaments to lie still and not become mentally restless. Dr. H. A. Pattison, in his *Treatment and Training of the Tuberculous*, cites an interesting example of the effect of occupation therapy on tuberculous patients. At the army tuberculosis sanatorium in New Haven, Conn., occupational therapy was tried in the ward containing the sickest white patients in the institution. "There was an almost immediate improvement in the symptoms and there was a marked improvement in the discipline and morale." Captain J. R. Byers, of the Canadian Medical Corps, states that he is firmly convinced that in the application of properly regulated work of an interesting nature in the treatment of pulmonary tuberculosis we have added a fourth word to our code which should read, rest, fresh air, good food, and work.

In prescribing occupational therapy for tuberculous patients, it is advisable to avoid all work which involves the extensor muscles of the arms and effort on the part of the trunk muscles. For such patients leather tooling and chip carving are considered among the most appropriate occupations. Pottery is also a very good occupation, while card colouring is both interesting and profitable.

In considering the special question of the possible danger of conveying infection through the handling of articles made by tuberculous patients, it is to be remembered that the instructions which every sanatorium gives and the hygienic precautions that such patients are taught to observe, render the liability to infection of articles handled by them very remote. To come down to a practical statement of the danger of infection with tuberculosis from clean patients employed in making articles for sale or use, it can be stated without fear of contradiction that the insignificance of the danger is comparable to that to which everyone is exposed in eating in a public restaurant or riding in a well-regulated public conveyance. However, to reassure purchasers or users of articles made by tuberculous patients, the following procedures are recommended.

Many textile articles will not be harmed by steaming, or by heat in a steam-jacketed steriliser. Failing this, pressing with a hot iron will effectually sterilise textile articles without injuring them. Basketry of various kinds, such as raffia, reed, wood splint, willow, etc., is used to a considerable extent in occupational therapy, and can be readily disinfected, if necessary. The qualification "if necessary" is made because the majority of baskets are finished by staining and varnishing, processes which would effectively kill any bacilli if, as is exceedingly unlikely, there were any on the articles. For baskets which are left in the natural finish, exposure to sunlight for a few hours without the intervention of glass between them and the sun will prove a complete germicide. Similarly with wood-work and leather.

For Cardiac Patients.

Many physicians would agree with the view that in no type of physical disease is the mental factor of so much importance in the recovery or rehabilitation of the patient as the cardiac, for hardly any other form of disease is associated with so much apprehension in the mind of the laity.

Occupational therapy for cardiacs may be divided into two classes: (1) for those with fair compensation and ability to do moderate exercise; (2) that which is more reconstructive and assists in carrying the patient through to wage earning and social living. In treating the first group extreme caution is imperative lest an overdose be given a patient in whose heart there exists decompensation. It should be remembered that cardiacs are notoriously difficult to gauge as to tolerance, so that prescriptions for occupations must be specific regarding the kind and amount of work. The patient must not be allowed to go beyond the limit allowed by his physician who is the only person capable of judging what this shall be.

For Surgical Cases.

With surgical cases there is as a rule proportionately less mental "let-down" than with medical. That is to say a smaller proportion of surgical cases are too sick to be benefited by occupation. We may divide surgical cases into two groups. First, those demanding immediate operation, as the injured and infected. Second, those in whom the operation may be deferred until the patient is in a proper physical and mental condition to undergo it. Examples, are chronic appendicitis, pelvic tumours, pelvic replacements and operations for deformities. Naturally the first group is not susceptible to any pre-operative occupational therapy. The latter group, however, may be greatly benefited by its application. In prescribing occupational therapy for surgical cases the choice of occupations will be governed by the type of injury or handicap which the patient has. It is impossible to lay down rules to cover all cases.

For Mental Patients.

In dealing with mental patients we are confronted with one of the most difficult problems of applying occupational therapy. Here the patients are "let-down" to a greater degree than in any other form of disease. Nevertheless, there is no other class of disability in which well-chosen and well-applied occupational therapy earns a better dividend. In the employment of occupational therapy many of the mental hospitals in England are lamentably behind the times and compare unfavourably with similar institutions in America. Indeed, in some of the mental hospitals in England occupational therapy as an organized therapeutic measure may be said hardly to exist. In the European Mental Hospital at Ranchi, occupational therapy has been the most

prominent feature of the various therapeutic measures employed there, ever since its inception in August 1923. To-day the organization and application of occupational therapy has reached a point at the Ranchi European Mental Hospital that has not yet been attained even in some of the best hospitals in America. There are various reasons to account for this, the principle of which is, in my opinion, that from the start we were fortunate in having the advice of Mrs. Eleanor Clarke Slagle, Director of Occupational Therapy for the State of New York. The vast experience and deep learning of Mrs. Slagle made it possible not only to avoid pitfalls in the beginning but to start the work on a proper basis. Then the Ranchi European Mental Hospital is fortunate in having ample accommodation for applying occupational therapy. To begin with there is a large central hall to which are attached annexes. In the main building the principal forms of occupational therapy are weaving, various kinds of needlework, knitting, boot-mending and making, drawing, raffia work, rug-making and producing books for the blind. In the annexes we have carpentry, basket-work, rug-making, sericulture, coir mat making and a blacksmith's shop.

In addition to treatment by graded and selected occupations, it is highly beneficial to place deteriorated patients under special habit-training instruction, whereby habits which are unpleasant or indecent are eliminated and more social behaviour substituted for them. To obtain success in this aspect of psychotherapy, there is need of the closest co-operation between all those who are concerned with the life of the patient. To arouse confidence and interest, to crowd out the old mental order of things is by no means an easy task. That it can be done is proven over and over again by the little stream of restored mental patients flowing back into the community with an adjusted outlook on life and social interests.

Work with mental patients naturally falls into distinct classes. The first being with the recoverable group, where every effort is concentrated upon a programme that will prevent deterioration and that will more quickly replace, by substitution, false ideas and beliefs by contact or interest in normal activities. The second class is that group where recovery may not be expected, and for whom active plans must be laid to utilize energy and productive ability in the hospital in which he in all likelihood will become a permanent member. The conservation of such mental capacity as may be possible is important in this group because we still may back our work effort with the hope that some cases are susceptible of great improvement.

The treatment by occupational therapy of patients suffering from nervous diseases requires the highest degree of individual attention and interest. Ingenious resourcefulness is taxed frequently in exacting sustained effort. Interest finally brings to the patient as well as to the

occupational therapist, the reward for faithful effort.

"It is difficult," writes Mrs. Slagle, "to invade the world of a mental patient and secure the co-operation necessary to produce results. Untiring patience, willingness to wait for the first faint glow and to know when the spark of attention is ready to burst into flame, is the duty of the occupational therapist. The ways and means of fanning the flame are manifold and, if the training or the occupational therapy has been adequate, he will know how best to help the physician in his work of restoration."

I would recommend those who are interested in this very fruitful manner of therapy to subscribe to the *Journal of Occupational Therapy and Rehabilitation*, the official organ of the American Association of Occupational Therapy, published bi-monthly by the Wilkins and Williams Company, Mount Royal and Guilford Avenue, Baltimore, Maryland, U. S. A. In this journal is an immense amount of information on every conceivable aspect of occupational therapy, from a practical as well as from a theoretical standpoint.

AN EARLY PIONEER ON THE STUDY OF INDIAN MALARIA.

By R. SENIOR-WHITE, F.R.S.E.,
Malariologist, Bengal-Nagpur Railway.

THROUGH the kindness of Mr. J. Van Manen, General Secretary of the Asiatic Society of Bengal, I have had my attention drawn to a most interesting old volume unearthed from the Society's library, entitled "Report on Fever," by Assistant Surgeon William Geddes, "published by Authority of Government, under the Inspection of the Medical Board," and dated Madras, 1827. It embodies the clinical observations of a keen observer, working over one hundred years ago at Seringapatam and Cuddapah, on regimental duties.

The 1st Battalion of the 11th N. I. arrived at Seringapatam in April 1823, and remained there for nearly a year. It had previously been stationed at Ellore for 18 months, and before that at Nagpur, in both of which stations the battalion had enjoyed good health. In spite of the fact that to reach Ellore it must have marched *via* the now defunct military road from Kamptee to Vizianagram, traces of which, such as an occasional milestone in the forest with "Raipur" still legible, or the mango topes and earthworks of camping grounds and forts, as at Ambadola, Rayagada and Asurgahr, still remain. This is the most notoriously unhealthy country in India, and though they apparently travelled through it about October 1821, whilst at Ellore the battalion had a low fever incidence, averaging only 22 cases per month on an average strength, excluding officers, of 1,119. On transfer to Seringapatam the fever incidence rose to 136 per month, or six times the Ellore rate. This works

out at 1,340 per mille per annum, as compared with 44.8 in the Bangalore brigade to-day, but of course the Fort of Seringapatam is no longer garrisoned.

The clinical thermometer had apparently not then come into existence,* and the author bases his observations on pulse rates plus simple statements of high fever or otherwise. He divides his cases into no less than eleven types, as under:—

Remittent	quotidian
"	tertian
"	ephemera
"	irregular
"	double tertian
Intermittent	quotidian
"	tertian
"	quartan
"	double tertian
"	ephemera
"	double quartan.

In addition the author deals with what he states may be styled a "double quintan," which he shows is really only a single tertian that is "anticipating," and elsewhere notes the particular tendency of this form to do this. The author's definition of an "intermission" is that the pulse should have come down below 72, the skin be perfectly cool and moist, and that there be little or no headache. From this it is easy to understand that this corresponds with the "apyrexial interval" of to-day, and that by a "remission" would be meant only a drop in the temperature chart.

Even faced with a quotidian fever, the author, to use modern terms, had in his own mind succeeded in distinguishing the species of causative parasite.

A quotidian occurring in the morning, he states, almost always turns out to be a double tertian. Even though the initial attacks occurred in the afternoon, a morning periodicity was later established. Quartan was, throughout, without a single exception in 44 frank cases of this disease, an afternoon fever. He notes that most quartans showed a quotidian periodicity in some part of their course. [There appears to be a *lapsus calami* on the first line of page 50. Unless here "quartan" be read for "tertian" the sentence does not make sense. The author states that the report has been greatly delayed by attacks of the disease he was himself investigating.] As a quotidian is thus distinguished from a double tertian, it becomes apparent that the former must have been in the main what we call to-day malignant tertian. Assuming this to be the case, we are left with the "ephemera" and "irregular" classifications to elucidate. The syndrome described on pages 18 to 19 would appear to be at least in part bacillary dysentery,

* The clinical thermometer was introduced into medicine some forty years ago by the late Sir Clifford Allbutt.—
EDITOR, I. M. G.

that described on page 32 dengue or tick-typhus. It is impossible to speculate with any certainty on the ætiology of these two classifications, and it will be safer to refer them to causes other than the plasmodia. Then from Table XII we may classify the parasitology of Seringapatam malaria as follows for the 1,503 cases listed in the table.

	Remittent.	Intermittent.	Total.
<i>P. vivax</i>	117	191	
double infection	56	..	364 = 32 per cent.
<i>P. malariae</i>	36	
double infection	8	44 = 4 "
<i>P. falciparum</i>	469	253	722 = 64 "
			1,130

The balance being regarded as non-malarial fevers.

Further parasitological information can be expected from the tables. By combining Tables VII and VIII, and using the above parasite differentiation, we get—

	PRIMARY ATTACKS.	
	Benign tertian.	Malignant tertian.
May	18	40
June	17	38
July	16	17
August	11	29
September	18	41
October	14	47
November	16	58
December	13	34
January	17	18
February	9	16
March	2	5

We here obtain corroboration of an attempt to express the author's classification in modern terms by seeing *P. vivax* maxima in May and September (the "spring" and "early autumn" rises) with a late *P. falciparum* maximum in November, (exactly what one would expect). The winter prevalence of quartan is seen in Table I, where 17 out of 27 recorded relapse cases of quartan occurred in January and February.

Now we have detailed information as to the parasitology of malaria at the Experimental Station at Nagenhalli, within two miles of Seringapatam (Knowles and Senior-White*), but only in children, not in adults, and it is known that quartan is peculiarly a disease of childhood. The Nagenhalli figures are *P. vivax* 53.5 per cent.; *P. malariae* 32.0 per cent.; *P. falciparum* 14.5 per cent.

Turning to the symptomatology, the author twice emphasizes the factor of constipation in precipitating an attack, whilst on page 20 he deals with the relationship of menstruation to relapse, a matter regarding which Lieut.-Col. R. Knowles and the present author, in another paper, have recently failed to obtain any definite information from their gynæcological brethren in Calcutta to-day. According to Dr. Geddes, however, "the

most frequent period of relapse is shortly before the occurrence of this discharge, and in one instance, the crisis on two attacks appeared to take place on the supervision of the menses, on each occasion four days previous to their regular period." One of the most extraordinary features of the report, however, is the very slight mention made throughout of splenic enlargement. The author deals with the point on page 29, and states that only on a few occasions has he encountered even perisplenitis, in a few more he encountered a "P. I." spleen, but "in one or two individuals also, a complete ague cake could be felt, and these were remarkable as not being in the situation of the spleen, but immediately under the integuments, below the margin of the ribs and considerably nearer the linea alba than the natural position of this organ, these cases, however, were very rare....." Now with few exceptions, the Seringapatam cases were not treated with quinine, and the fever only ceased by the development of partial tolerance or increasing resistance. How then was it that so little splenic enlargement was encountered? No less than 45 out of 748 original cases had four or more relapses (Table II), and surely at least these 45 would have shown the author splenic enlargement. The author notes that usually the "crisis" was reached after the third paroxysm.

James' recent observations on the irregularity of initial attacks made in connection with G. P. I. treatment were anticipated by Geddes, particularly in respect of quartan. "The quartan period seldom occurred distinctly from the commencement of the disease.....it more generally was observed after several irregular paroxysms, and occurring at all hours—chiefly of the quotidian type, but sometimes of the tertian, and in these the tertian paroxysms were generally observed at the hour of quartan.....whilst the quotidian accessions were very infrequently in the forenoon; with these was occasionally blended a quartan interval, and after a few of these irregularities, the disease puts on its regular quartan type, with all its obstinacy in resisting the means used for its removal." He notes that only 3 out of 36 fresh quartan infections were frankly quartan from their onset, whilst he further anticipates James' observations on multiple infections made with *P. vivax*, that double infections of quartan tend to later become single.

A curious line of enquiry prescribed by the author, arising from local lay beliefs in old European residents of "Mysore and Seringapatam," is the relationship of relapses to the phases of the moon, and in Table IV he presents some definite evidence that incidence is highest on the 15th of the lunar cycle. He is distinctly sceptical as to whether there is anything in the hypothesis, the more so as he found that native beliefs took no account of the phenomenon, but there is all the material for a nearly regular curve in Table IV!

In discussing the course of fever, the author's observations are interesting. He notes, for

* In Press.

Mysore, a relationship with jungle and elevation. He states that for Seringapatam no sufficient cause of its malariousness can be discovered, as elsewhere he has met, with a river bed and adjacent paddy fields without producing conditions of such extreme unhealthiness—and we would urge on the Malaria Section of the Mysore Health Department an investigation into the accuracy of these statements, having regard to old maps of the Cauvery irrigation system in the vicinity as well as conditions to-day. He notes that the most unhealthy periods coincide with east winds. This may merely mean the north-east monsoon in the usual autumnal "fever season," or it may mean a wind-borne influx of mosquitoes from the irrigation area of Nagenhalli, if such existed in 1823. The upward leap in spleen rates as this area was entered along the Bangalore-Mysore road was demonstrated to the writer by Dr. Sweet a year ago.

At the end of his year with the 11th N. I. the author was transferred to Cuddapah, where he apparently became a sort of Assistant Civil Surgeon, being also in medical charge of the "1st Extra Regiment," and the jail. Here he encountered a type of disease that he did not meet with at Seringapatam, to wit "typhoid remittent," and it appears that it is to Geddes that medicine is indebted for the term, as after describing it he states, "I conceive that the term typhoid remittent may be properly applied to it." He then gives a clear account of cerebral malignant tertian, terminating fatally. He notes how these patients had frequently attempted to carry on duty whilst sick for several days after being attacked. He also notes visceral malignant tertian with choleraic symptoms. However, Geddes was apparently not clear about the distinction of this form of malignant tertian from heat stroke.

Perhaps the most interesting aspect of the book, however, is the details it contains regarding treatment. This was the period of calomel as the standard remedy for malaria, as detailed in Knowles and Senior-White's *Malaria*, page 89. The author's earlier period at Seringapatam shows him in possession of cinchona bark powder only, and not altogether enamoured of it; the Cuddapah period shows him in possession of quinine sulphate, albeit apparently in very limited quantities, and enthusiastic about its use. He writes, ".....the foetid, ulcerated and often bleeding mouth caused by this medicine, the protracted convalescence in consequence, the frequent affections of the bowels by the calomel and perhaps the tendency to relapses excited by it, have all made me very reluctant, latterly, to make use of mercury.....my opinion in regard to this medicine in fever is as follows; that in intermittents and chronic remittents it may always be superseded by the sulphate of quina where procurable, or in most cases by the pulv. cinchonæ; in remittents, when mild and critical.....it is not necessary; in typhoid and other more violent remittent, the sulphate of quinine is much more

likely to be successful, and in short, that the use of mercury to salivate a feverish patient..... must in every instance be considered as an acknowledgment that our other more powerful means are not available."

Geddes arrived at this conclusion from cases such as the following, which vividly illustrate the horrors to which the unfortunate malaria patient was subjected a century ago. This particular case was not Geddes', but was under J. Bell, Assistant Surgeon, 42nd Regiment N. I., at Ghooty.

"Febris Biliosa Remittents.

"Henry Marshall, Ensign, Aetat, 17.
Six months resident in India."

4th January, 1827.—The patient was attacked suddenly. He came to hospital as soon as the attack commenced, after rigors lasting an hour.

"Pulse 84, skin hot and dry; tongue white, bowels regular." In spite of the last case note, the unfortunate youth was immediately placed on the following:—

℞			
Mag. Sulph.	℥ss.
Antim. Tartrate	gr. iv.
Every two hours.			

℞			
Hydrarg. Submur.	gr. xij.
Pulv. Jacobi	gr. iv.
Opii	gr. j.
Bolus at bed time.			

℞			
Inf. Sennæ	℥ii.
Mag. Sulph.	℥iv.
Extr. Colocynth	gr. vi.
Aq. Ment.	℥i.
Haustus cras mane cap.			

5th January.—"He slept well and perspired profusely during the night. The medicines operated freely, bringing away several copious dark coloured stools. Pulse 80, soft and compressible, tongue white in centre." In the afternoon he had another rigor, followed by a pulse of 108, with all the symptoms of acute pyrexia. He then got "Venæ Sectio ad ℥xxiv. Rept. Bolus Hydrarg. Submur. c Pulvere Jacobi et Opio hora Somni et Haustus Purgans cras mane. Contr. Mistura ex Magnes. Sulph. et Antim. Tart."

6th January.—"He was much relieved by the bleeding, and slept well during the night. He had two copious dark coloured stools from the medicines, pulse 96, sharp, tongue dry, white and excited, skin hot with slight moisture on the forehead and upper hip, urine high coloured and scanty, moans deeply at times."

In the evening, there was a great exacerbation, pulse 120, and a complaint of violent pains in the head, etc. He therefore got "Venæ Sectio ad ℥xxiv. Contr. Mistura ex Magnes. Sulph. et Antim. Tart. Rept. Bolus Hydrarg. Submur. c Pulvere Jacobi et Opio et Haustus Purgans ut Antea."

7th January.—The morning case notes of 6th January are repeated almost verbatim, except that thirst was noted as less urgent, but in the evening there was a further paroxysm, pulse 120, with stupor.

"Hirudines xxiv statim Temporibus.

Rept. Bolus et Haustus Purgans ut Antea.

Contr. Mistura ex Magnes. Sulph. et Antim. Tart."

8th January.—"The leeches afforded great relief, he had several dark watery and foetid stools from the medicines, pulse 120, tongue dry, and covered with a dark fur, skin very hot and of a deep yellow tinge. He moans very frequently, there was a slight remission of fever at 12 o'clock noon, when the pulse fell to 100, and there was slight moisture in the forehead and upper lip; this was succeeded by an exacerbation of symptoms, he became restless and irritable, thirst very urgent, burning heat of skin, occasional aberrations of mind, urine high coloured, scanty, and passed with such difficulty as to require fomentations to make it flow.

Contr. Mistura ex Magnes. Sulph. et Antim. Tart.

Rept. Bolus hora Somni. et cras mane."

9th January.—He continued in much the same state all day, pulse during fever 125, during remission 100, tongue quite dry, with dark fur, deep red at point and edges. Semi-delirious.

As he apparently was considered to have not even yet taken enough mercury, he now received:

"Contr. Mistura ex Magnes. Sulph. et Antim. Tart.

Rept. Bolus bis in die. Frictiones ex unguent. Hydrarg. zj. in die."

10th January.—In the same state. Same remedies, including the mercury inunction.

11th January.—"No alteration for the better, pulse 130, skin hot and of a deep yellow colour, tongue quite dry and covered with a dark chocolate coloured fur, and when touched it feels as rough as a nutmeg grater, urine scanty and passed with difficulty, stools frequent, watery, dark and very foetid."

Quinine was now apparently exhibited as a last resort.

"R Quinine Sulph. gr. xij. Micæ panis aquæ aa qs. ut. ft. pilul. xij. quarum, Sumat unam ad remissionem febris, et repetatur aquaque hora febre absente."

The pills had the desired effect of bringing on an intermission of fever. The pulse fell to 98, and all the symptoms were relieved....."

"Omitr. Bolus et Frictiones ex unguento Hydrargyri.

Rept. Mistura ex Magnes. Sulph. et Aatim. Tart. ad accessionem Febris.*"

12th January.—A very violent paroxysm occurred, with full delirium of a maniacal nature. Towards daybreak he fell into a torpor, pulse

135, with a remission to 108 and slight lowering of temperature at 8 a.m.

"Sumat Pilulas Quinæ Sulphates tres ad remissionem febris, et postea duas quaque hora febre absente.

Rept. Mistura Magnes. Sulph. et Antim. Tart. ad accessionem febris."

The pills again acted like a charm. Pulse down to 96, skin cool and suffused with gentle perspiration. "He complains that his gums are swelled and very tender—his bowels were twice opened, stools contain healthy bile and are less foetid. He is excessively reduced and so much exhausted as to be unable to move in his bed without assistance."

13th January.—No return of fever. Mouth very sore, ptyalism commenced. [The author has elsewhere noted that mercurial symptoms usually hold off until the fever has broken.] Quinine continued.

14th January.—No return of fever. "Ptyalism is very severe and he has much difficulty in opening his mouth owing to pain and swelling of the glands under the jaw." Quinine continued.

From this date he gradually improved, but relapsed,† with tertian intermittent on 12th February, when almost well, "in consequence of exposing himself to the sun." This again yielded to quinine, of which he received 92 grains in four days. It is noted that 24 grains of quinine sulphas. entirely removed the attack of tertian intermittent.

The case is completely by a note by the Medical Board at Madras, who appear impressed but not convinced. It is followed by a very similar but much less severe case where quinine nearly failed, as noted by the Board, owing to its being exhibited in totally insufficient quantities by a Surgeon Stephenson of the 2nd Light Cavalry, who ordered only gr. ijs. t.i.d., later changed to gr. iij. b.i.d., the fever continuing for about three weeks under this regimen.

Surgeon Stephenson finally forwarded a report on quinine to the Superintending Surgeon, Hyderabad Subsidiary Force, protesting against the Medical Board's order to exhibit it at the rate of gr. xx. a day. This note is dated 4. xi. 22, whereas the note of scepticism on "Henry" Marshall's case is dated 19. iii. 27, so we may deduce that it was in the year 1827 that the Medical Board became convinced of the value of quinine in malaria. It must have been due to the acute observations of men like Geddes and Bell that this radical change-over in medication occurred, and the fact that other officers' cases are appended to Geddes' book shows how highly he must have ranked in his day as a malarialogist. Seventy years before his great successor in the same Service and Province, he must, to have

*Total amount of mercury exhibited to this date: by the mouth 108 grains, by inunction, 5iii.

† Was this a relapse, or a benign tertian infection? If the former, then it throws great doubt on the possibility of separating the two tertians other than by microscopical methods, and vitiates the whole argument on p. 161.

accumulated the observations here summarized, have imitated him.

"I pace and pace, and note down all I see,
Lest some dim distant light may haply break."

Can anyone in the Surgeon-General's office in Madras discover the ultimate fate of this pioneer malariologist, and if, as is probable, he left his bones in India, where he lies?

Medical News.

A BILL TO ESTABLISH AN ALL-INDIA MEDICAL COUNCIL.

As our readers are aware, the present position with regard to the relationship of the Indian universities to the General Medical Council of Great Britain has reached a serious *impasse*. In 1926, Dr. U. Rama Rau of Madras introduced a Bill "to regulate medical education in India" in the Council of State. As, however, Government were convinced of the imminent need for setting up in India a central organisation to regulate the standards of medical qualifications, this Bill was dropped in favour of the official proposals. The attempt on the part of Government to introduce its own Bill in the Legislative Assembly, however, proved abortive, as unexpected opposition was encountered, chiefly from Provincial Ministers, who appeared to be afraid that the proposed central organisation might override and usurp the functions of the provincial Medical Councils. The General Medical Council then proposed that a Commissioner of Medical Qualifications for all-India should be appointed, who would do the necessary inspection work on their behalf, and report as to whether or not the term of recognition of the Indian medical degrees should be extended. This proposal was vetoed by the Legislative Assembly.

As a result, the present position is that recognition of the Indian medical degrees by the General Medical Council of Great Britain only holds until the next meeting of that Council (February, 1930), when the whole subject is to be discussed.

We can understand opposition to the proposal for a Commissioner of Medical Qualifications, though we consider such opposition to be unsound. From the point of view of the General Medical Council, it is absolutely essential that the standard of examination shall be a sufficiently high one, and not even the degrees of the British universities would be granted recognition if the Council were not satisfied that this was the case. On the other hand, the trend of present-day opinion in India is against the increase of officialism, and such a Commissioner cannot by any stretch of the imagination be regarded as a democratic institution.

Opposition to an all-India Council is less easy to understand. There does not appear to be any real danger that such a Council would override the provincial ones. With Medicine a transferred subject, the provincial councils are in a fairly strong position. We believe that there is a consensus of opinion, both among the medical profession in India and amongst the lay public, as to the need for such a Council, whilst its creation would once and for all meet the requirements of the General Medical Council of Great Britain. It would give India self-government in medical education, together with reciprocity with Great Britain.

It seems doubtful at the present moment whether Government will re-introduce the Bill for an all-India Medical Council in the Assembly, but some action must be taken to meet the situation which has arisen.

Under these circumstances Dr. Rama Rau hopes to re-introduce a Bill for this purpose, modified from his former proposals to meet the criticisms which the former proposal evoked.

The purposes of such an all-India Council in the Bill are defined as follows:—

(1) The establishment throughout British India of a uniform and satisfactory standard of medical education and examination.

(2) To establish an all-India medical register of qualified medical practitioners.

(3) To determine the qualifications necessary for enrolment on the register.

(4) To scrutinise and approve of the courses of medical study and examination by different institutions, and to inspect their examinations.

(5) To attain a status for the medical profession in India which will ensure recognition of its members in the United Kingdom and elsewhere, and secure reciprocal rights of medical registration.

(6) To regulate the conditions under which persons qualified to practise in the United Kingdom and elsewhere may be admitted to the all-India register.

The composition proposed for the Council is as follows:—

(1) The President, in the first instance, to be nominated by the Governor-General in Council; thereafter to be elected by vote of the members of the Council.

(2) One member elected by each university established in British India by an Act and having a medical faculty.

(3) One member from each province elected by private practitioners who are graduates of a recognised Indian university.

(4) One member from each province elected by private practitioners who are on the provincial register, and who hold qualifications other than (3) above.

(5) One member from each province to be nominated by the Governor-General in Council.

The usual term of office of the president and members to be normally four years.

The usual definition of the rights and privileges of medical practitioners on the proposed all-India register are then defined, and follow upon the usual lines, e.g., certificates from any persons not on the register shall not be valid in law, and appointments to official posts shall be confined to those on the all-India register. Finally, similar powers are proposed for the all-India Council with regard to erasure of names of persons guilty of improper conduct in a professional sense from the register, as are in force under the General Medical Council of Great Britain. The right of appeal, whether in person or by counsel, however, is retained.

On a study of Dr. Rau's Bill, our opinion is that it appears to meet the present conditions admirably. It meets the Indian demand for self-government in medical affairs by the creation of an all-India body of democratic constitution, to whom the General Medical Council of Great Britain may be expected to entrust the duties of supervision of medical education and inspection of examinations; whilst it does away with the necessity for an official Commissioner of medical education, appointed *ad hoc* without consulting general medical professional opinion in India. The one direction in which opposition to the Bill is likely to develop appears to be the suggestion that the all-India Council may override the provincial Medical Councils. We believe that this danger is more apparent than real. Normally, the right of inspection of medical study and examinations would be exercised, but we doubt whether the right of erasure of names from the medical register would be exercised, except with regard to the names of persons reported to have been erased from the provincial medical registers. Undoubtedly the proposal for an all-India Council suggests a duplication of functions by a central all-India body and by the provincial councils, but in actual practice we doubt whether difficulties would arise. On the other hand, the medical profession in India would gain immensely by the creation of a democratic all-India Council which would be an intermediary between itself and the General Medical Council of the United Kingdom, and would ensure uniformity in the different provinces in India, and between them and other medical councils in the British Empire and other countries. In brief, the Bill

attempts a sort of Federal solution of the present problem, which would leave the powers of the existing provincial councils untouched, but yet introduce a central and co-ordinating mechanism which would give India combined representation with regard to world problems of medical education and registration.

We have no doubt that the proposed Bill may be considerably modified when it actually comes to be discussed; but it, or some such similar Bill, appears to be absolutely essential to meet the necessities of the present situation.

THE NEW YEAR HONOURS, INDIA, 1930.

The following were the New Year Honours conferred on 1st January, 1930, on medical workers in India, whose recipients we beg to congratulate.

C. B.

Colonel A. B. Fry, C.I.E., D.S.O., M.D., V.H.S., I.M.S.

C. I. E.

Colonel W. V. Coppinger, D.S.O., M.D., F.R.C.S.I., I.M.S., Inspector-General of Civil Hospitals, Central Provinces.

Lieut.-Colonel A. F. Hamilton, M.B., F.R.C.S., I.M.S., Professor of Midwifery, Grant Medical College, Bombay.

O. B. E.

Major A. B. De Souza, I.M.D., Resident Medical Officer, Gokuldas Tejpal Hospital, Bombay.

D. H. J. Nicholas, Esq., I.M.D., In-charge of Government House Dispensary, Madras.

KAISAR-I-HIND MEDAL.

(1st Class.)

Sister Josephine, Sister-in-charge of J. J. Hospital, Bombay.

Miss M. Longmire, M.B., Ch.B., Lady Doctor in-charge of the Church of England Zenana Missionary Society Hospital, Khammamett, Warangal District, Hyderabad, Deccan.

The Reverend W. S. Sutherland, Superintendent, Lady Willingdon Leper Settlement, Chingleput, Madras.

(2st Class.)

Miss E. G. Barton, Matron, C. E. Z. M. Hospital, Bombay.

Subadar G. Haidar, I.M.D., Senior Sub-Assistant Surgeon, Indian Military Hospital, Nowshera.

Miss Lilawati, Lady Health Visitor, Punjab.

Miss M. W. H. McNeil, Superintendent, Christina Rainy Hospital, Madras.

Miss B. Thungamma, Lady Doctor in-charge of the Ishwari Memorial Hospital, Benares, United Provinces.

Charles E. Vail, Esq., Surgeon and Physician, American Presbyterian Mission Hospital, Miraj, Bombay.

KHAN BAHADUR.

D. J. E. Behram, L.M. & S., Honorary Secretary, Parvatibai Leper Asylum, Surat, Bombay Presidency.

Khan Sahib M. Asghar Ali, Assistant Inspector-General of Civil Hospitals, Punjab.

RAI BAHADUR.

Pandit P. Pant, I.M.S., P.M.S., Officiating Civil Surgeon, United Provinces.

Rai Sahib Subedar Major and Honorary Lieutenant Lachman Dass, Sub-Assistant Surgeon (Retired), Baluchistan.

KHAN SAHIB.

Syed H. Shah, Senior Sub-Assistant Surgeon, Civil Dispensary, Mozang, Lahore, Punjab.

Maulvi M. Abdulla, Sub-Assistant Surgeon, Baluchistan.

RAI SAHIB.

Lala B. P. Gupta, L.M.P., Medical Officer-in-charge, Shahabad Dispensary, Hardoi District, United Provinces.

Mr. Aya Ram, Sub-Assistant Surgeon in-charge, Kyaukme and Sakantha Dispensaries, Hsipaw State, Northern Shan States, Burma.

Babu Shiva Prashad, Sub-Assistant Surgeon, Bihar and Orissa.

Bo T. Kazi, Sub-Assistant Surgeon, Gyantse, Sikkim.
Subadar Major A. P. Misir, I.M.D., Senior Sub-Assistant Surgeon.

RAO SAHIB.

S. M. Khedkar, Subordinate Medical Service, Sholapur District, Bombay Presidency.

THE 37TH CHEMISTS' EXHIBITION.

THIS Exhibition, organised by the *British and Colonial Pharmacist*, was established in 1896 in London, and there is nothing approaching it in size and comprehensiveness held anywhere else in the world. It was organised to give the practising pharmacist an opportunity every year of seeing, under one roof, all the goods he sells and the various apparatus, utensils and other requisites he uses in his profession. The management is always delighted to welcome visitors from the Dominions and Colonies, and such gentlemen will be admitted on presentation of business card. The Exhibition has grown continuously, and this year will be housed from 26th to 30th May, in the handsome new Hall of The Royal Horticultural Society, Westminster, S.W., in the very heart of London, practically under the shadow of the Houses of Parliament and Westminster Abbey.

THE BRITISH COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS.

Lieut.-Col. V. B. Green-Armytage, M.R.C.S. (Eng.), L.R.C.P. (Lond.), M.B., Ch.B. (Bristol), M.D. (Bristol), F.R.C.P. (Lond.), I.M.S., Professor of Obstetrics and Gynaecology and Surgeon of the Eden Hospital, Calcutta Medical College, has been elected a Foundation Fellow of the British College of Obstetricians and Gynaecologists. Our readers will join us in our congratulations to him on so well deserved an honour, which is not only a personal one, but also a tribute to the Indian Medical Service, and to the work done at the Eden Hospital, Calcutta.

Current Topics.

Remarks on the Symptoms and Diagnosis of Placenta Prævia: with a Note on the Use of Submammary Saline.

By BETHEL SOLOMONS, M.D., F.R.C.P.I., M.R.I.A.

(*The Brit. Med. Journ.*, September 21st, 1929.)

1. THE most likely reason for separation is that the painless contractions of Braxton Hicks, which continue during the whole pregnancy, cause a passive dilatation of a lower segment which is softer and more dilatable than normal; during the later months of pregnancy the placenta does not expand with it and must therefore become detached.

2. Disease of the placenta may occasionally be a causal factor from faulty adherence, and it is a well-known fact that the placenta may be diseased.

3. The capsular development of the placenta may prevent the attachment being as firm as usual.

Hand-in-hand with these theories are: (1) the opened placental site sinuses pouring out blood after separation; (2) hæmorrhage occurring from the circular sinus and the intervillous spaces of the placenta.

These are the most plausible of the many theories suggested.

ÆTIOLOGY.

The most valuable factor in considering ætiology is to determine if the knowledge will assist in diagnosis or prevention. The following theories must be mentioned:—

1. The basal implantation theory. That the ovum after fertilization is inserted in the lower uterine segment.

The placenta is basal and the clinical result is a central placenta prævia.

2. The capsularis implantation theory. That the placenta is developed in connection with the decidua capsularis as well as with the decidua basalis. This variety determines a lateral or partial placenta.

3. Defective vascularity of the decidua may make it necessary for the placenta to spread over a large area for nourishment.

4. Inflammatory or atrophic changes may be explained in a similar manner.

5. The placenta membranacea may invade the lower segment because of its size.

These are the theories which are really worth considering and they bear out the one great theory that there is some fault in the endometrium—a true endometritis or else a hyperplastic condition, and that this may account for the abnormality. We have several times in our practice curetted the uterus two months after the occurrence of placenta prævia and have obtained the above findings. Following the growth of healthy endometrium, confinements have been normal. In other words, in the basal theory the ovum seeks healthy endometrium; in the capsularis theory the ovum must spread. There is no need to explain further the other possibilities. While we are not at all wholesale advocates of the curette, we believe it to be entirely indicated two months after a placenta prævia labour when the uterus has regained its pre-pregnancy tone, and that by so doing placenta prævia in future pregnancies will be avoided.

THE DANGERS OF PLACENTA PRÆVIA.

These, according to world statistics, are great for the mother and very great for the child. The mother may die from collapse following on hæmorrhage, from which, if she recovers, she is so desanguinated that sepsis of a fatal nature may occur. Sepsis may also occur because of the low position of the placental sinuses. It is scarcely necessary to mention that sequelæ such as menorrhagia, tendency to abort, and sterility are numerous. In addition, rupture of the cervix because of its sodden condition is said to be common.

The foetal mortality is enormous. Prematurity with a 50 per cent. death rate in the first month is the rule and this fact must be carefully borne in mind when dealing with diagnosis with a view to treatment. Death during its passage through the birth canal is common for the infant because of interference with its oxygen supply through the placenta, or else from prolapse of the cord.

The possibility of the occurrence of placenta prævia is made very evident when it is stated that in a search of the records of the Rotunda Hospital it was found that there were 326 cases among 60,130 deliveries—that is, an incidence of 1 in 183. This incidence makes very apparent the necessity for knowledge of the subject by every general practitioner. Among these cases there were 19 deaths, a death incidence of 1 in 17. This mortality rate is far too high, and with improved technique in diagnosis and treatment, I am able to report a series of 55 consecutive cases since the commencement of my Mastership without mortality. Most of the babies were premature and only 12 were born alive; 2 died before leaving the hospital, so that the prognosis for the infant is extremely bad. These statistics show clearly the necessity for deep thought when deciding on treatment of a given case.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS.

The occurrence of placenta prævia may be suspected in pregnancy by the history of hæmorrhages at various times. A perusal of the case sheets of the hospital reveals in many instances a history of hæmorrhage occurring at intervals varying from the fourth month onwards. This point may be of value, for placenta prævia may be suspected, and the patient should be kept at rest, when it may be found possible to carry her on in her pregnancy until the child is well viable.

A history of previous abortions or miscarriages is sometimes elicited, but this history has been obtained so

seldom that it has but slight, if any, significance. It has been suggested that, as the patient is usually multiparous, something might be elicited from the previous labours; no such facts could be made out. On the contrary, with the exception of abortions, the previous labours had, as a rule, been without incident. Repeated toxæmias are common; placenta prævia seldom occurs more than once in a woman's life. We have little or nothing to warn us of the possibility of placenta prævia. In its silence lies danger. How, then, can we diagnose the condition? The first symptom to which our attention is drawn is fresh hæmorrhage accompanied by clots. This is a most important point in diagnosis; the bleeding is extremely insidious in its onset; it may occur in sleep; it may happen while the patient is sitting talking to her friends; it may be slight and may recur, or the first hæmorrhage may be so severe as to cause marked constitutional symptoms, even to the extent of a fatal issue. We have met with patients whose pulse was 80 and strong one moment, and who soon after were pulseless. The bleedings are entirely unaccompanied by pain. This severe type speaks for itself and tells us the diagnosis; the patient who has recurrent attacks of slight hæmorrhage is more difficult, but her case must be diagnosed as soon as possible, for a slight first hæmorrhage does not mean that the next will not kill her. In fact, generally speaking, definite diagnosis is essential; a "wait and see" policy may mean a fatal result. The infant is usually premature to some extent. A study of the records revealed the fact that there was no special week more favoured than another. At any period from twenty-eight to forty weeks the hæmorrhage may commence.

Following the hæmorrhage, two pints of submammary saline are given under the breasts. As this takes place during the diagnosis it must be mentioned here, even though it is a part (and a most important part) of the treatment. All practitioners should carry in their maternity bag apparatus for giving submammary saline; it is the most practical method of making up for the blood lost—in the hands of the ordinary general practitioner—and it is entirely effective. Since I have adopted this prophylactic saline method at the Rotunda I have not lost a single case. People may speak of blood transfusion and venous medication, but in the emergency practice of the general practitioner a combination is necessary which is simple, safe, and effective. Once the saline is started, its administration should, if possible, be left to an assistant. At the Rotunda the saline is prepared as follows: one pint of water is boiled with two teaspoonfuls of salt; this is kept in stock solution. When required one pint of boiling water is added; this gives the correct strength and approximately the correct temperature (about 100°F.). In practice the proprietary Soloids of salt may be used. The abdomen is examined and the following facts are found: (1) that the uterus is soft and painless; (2) that the presenting part is high and unfixed, and gives the definite impression that it is sitting on something; (3) a uterine souffle is heard in the region of the hypogastrium. Some authorities have suggested that the diagnosis is now made: painless bleeding, prematurity, soft painless uterus, high presenting part, uterine souffle, clotted blood. We do not subscribe to this dictum. These cardinal facts suggest the abnormality; they do not make the diagnosis definite. We hold that the only way to make a definite diagnosis is to examine the patient by the vagina. Before making this examination the doctor should have decided on his next step, for he can at any rate have made a provisional diagnosis; the vaginal examination may cause hæmorrhage, and it may be necessary to treat the case immediately the vaginal examination is concluded. In placenta prævia, more than in any other condition, must a vaginal examination be made under extreme aseptic precautions. Sepsis is more than possible, but the danger of missing the diagnosis without vaginal examination is greater than the danger of sepsis. If the cervix is closed, the low implantation may be suspected by a boggi-ness in one or all of the fornices. If the os is open, the placenta itself is felt. It is indeed simple to diagnose the placenta; we advise our students to familiarize

themselves with the touch of a normal placenta, when the diagnosis of a prævia is simple.

An examination of the urine should be made in all instances; it will probably be found to be normal. Toxæmia is seldom an accompaniment of placenta prævia, although as an exceptional circumstance it may be so. This exception must be specially stressed; when present, it is most common in the primigravida, and the case will be a typical placenta prævia with toxæmic symptoms.

Differential Diagnosis.

There are many differential points in diagnosis when a woman bleeds in the last three months of pregnancy:—

1. Accidental hæmorrhage.
2. Excessive show.
3. Varicose veins in some part of the tract—for example, vulva, vagina, cervix.
4. Hæmorrhoids.
5. Carcinoma of the cervix.
6. Polypus.
7. Erosion of the cervix.

In addition it may be necessary, on examining the abdomen and finding the "high head," to diagnose from: disproportion; and, on vaginal examination, from hydrocephalus, anencephalus, vasa prævia, and cervical varix.

Most of these are soon cleared up. An excessive show may always be confused with any variety of ante-partum hæmorrhage; its diagnosis is made by the speedy cessation of the hæmorrhage, accompanied by the absence of physical signs of placenta prævia. Varicose veins of the vulva or vagina will readily be seen; the same applies to the bleeding from hæmorrhoids. Occasionally an erosion of the cervix or a polypus may bring about symptoms suggestive of placenta prævia, but the erosion and polypus are visible through a speculum. Carcinoma of the cervix will be accompanied by history and physical signs. Occasionally one meets in a primigravida a condition of "high head" which is suggestive of disproportion. The commencement of the cardinal symptoms of placenta prævia suggests this abnormality, but a careful examination must be made to confirm the diagnosis. We have had a case lately at the Rotunda where the placenta acted as a mechanical cause of delay in labour, and this was perfectly evident at the Cæsarean section operation which was indicated later. It is only necessary to draw attention to this differential point in diagnosis, and to remember that occasionally the two may occur together.

Hydrocephalus must be mentioned, for the enormously separated fontanelles may give the impression of a cervix with placenta protruding through. In addition the height of the head when felt by the abdomen may give a wrong impression. Anencephalus may simulate anything. Vasa prævia may suggest placenta prævia, but it is unimportant.

The condition which is most frequently mistaken for placenta prævia is accidental hæmorrhage, and since the treatment for each of these conditions is very different, and as the treatment for the one is entirely unsuitable for the other, the importance of making a correct diagnosis is obvious. It is well at this stage to consider the various factors in making a diagnosis between the two.

(a) *Parity*.—Placenta prævia is more common in the multipara than in the primigravida, but it is found in the primigravida. Accidental hæmorrhage is always found in the multiparous patient.

(b) *Toxæmic symptoms* are nearly always present in accidental hæmorrhage, and they are usually absent in placenta prævia. In spite of this assertion it is necessary to give a warning: accidental hæmorrhage may occur without toxæmia, and severe toxæmia accompanied by placenta prævia may arise. During the past year a patient who was being carefully observed during her pregnancy developed albuminuria near the end. She was admitted to hospital, and efforts were made to overcome the toxæmia. The albuminuria never disappeared, and a week before term all symptoms of placenta prævia were present. We were dealing with a hugely fat primiparous patient with albuminuria, a one-finger cervix, and central placenta prævia. For this rare combination of circumstances there was only one treatment—Cæsarean section.

In this exceptional case the diagnosis was difficult. It was made without vaginal examination, and confirmed by a vaginal examination immediately before operation.

(c) *Period of pregnancy*.—Accidental hæmorrhage varies. Placenta prævia more commonly occurs as a premature birth.

(d) *Pains* are a usual accompaniment of accidental hæmorrhage; they are always absent in placenta prævia.

(e) The *abdomen* is tense, and the presenting part is fixed in accidental hæmorrhage; while in placenta prævia there is a flaccid abdomen with malpresentation or non-fixation of the presenting part.

(f) The *fœtus* is dead in the majority of cases of accidental hæmorrhage; it is alive at the commencement of labour in placenta prævia.

(g) The *hæmorrhage* which occurs in accidental hæmorrhage is continuous and is blood-stained serum; it has been squeezed out of the uterus like the juice from an orange. The hæmorrhage in placenta prævia is fresh clotted blood, which may come in gushes and varies in amount.

Finally, in discussing differential diagnosis we must refer to a type of case occasionally encountered and already mentioned. A woman who is eight months pregnant suddenly pours blood, becomes collapsed, with imperceptible pulse and other accompanying symptoms. Does one waste time in diagnosis? No, for it is nearly certain. She is immediately given treatment for collapse, while pledgets of cotton-wool are boiled in a saucepan; these are used to stop the hæmorrhage, and the absolute diagnosis is made later when the collapse symptoms have disappeared, and therefore when the patient is ready for active treatment.

PROGNOSIS AND DANGERS.

The prognosis where a case has been correctly diagnosed and treated is excellent; in fact, we feel we may borrow an apt aphorism on another subject, and say "our patient should not die from placenta prævia."

There are dangers, both immediate and remote. Death from collapse following hæmorrhage is possible. Death from sepsis from manipulations, low implantation, and diminished vitality must be feared. Anæmia may last for some time, and the patient should be allowed to recover thoroughly from a placenta prævia confinement before embarking on another pregnancy. Contrary to the experience of others, neither adherent placenta nor post-partum hæmorrhage has been found common with our patients.

To our mind, the prognosis depends on diagnostic ability with choice and technique of treatment. Treatment does not come within the scope of this communication.

SUMMARY.

1. It is difficult to separate diagnosis from treatment.
2. Nomenclature, both with regard to period of pregnancy and situation of placenta, is considered.
3. Rigby of Notts should be given priority in making a diagnosis between placenta prævia and accidental hæmorrhage.
4. A pathological condition of the endometrium is a fruitful cause of placenta prævia. Curettage should be done before the next pregnancy.
5. The incidence of placenta prævia in 69,000 deliveries was 1 in 183, while the mortality was 1 in 17. There has been no mortality at the Rotunda Hospital in the last 55 cases.
6. Although there are others, accidental hæmorrhage is the important condition to diagnose from placenta prævia. The methods of doing so are given.
7. Prophylactic submammary saline is an essential part of treatment during the diagnosis.
8. Toxæmia is not a usual accompaniment of placenta prævia; an exceptional case where it occurred is mentioned.

We shall conclude by saying that the whole paper might have been summed up in a few words as follows: That the symptoms and diagnosis of placenta prævia might be written down—an absolutely painless clotted hæmorrhage, insidious in nature, some time in the last

three months of pregnancy. It seemed necessary, however, to refer to some salient points in order to remind ourselves and the world that women may be saved by a careful and exhaustive diagnosis which leads to correct treatment and a satisfactory result.

Observations on Diagnostic and Other Errors in Questions of Venereal Disease.

By L. W. HARRISON, D.S.O., M.B., CH.B., F.R.C.P. (Ed.).
(*The Brit. Med. Journ.*, September 14th, 1929, p. 483.)

THE subject of this paper was suggested to me by a run of such cases as the following:—

A man of good position asked me to examine him for gonorrhœa. He said that a year previously he had contracted gonorrhœa, which had cleared up completely without any complication. About three months before I saw him he had married, after passing careful tests by a conscientious specialist. A month after marriage his wife developed a Bartholinian abscess, and on the strength of this the husband was told that he had infected his wife with gonorrhœa. You can imagine his distress. I examined him three times and failed to find any evidence of disease in his urethra or adnexa. A complement fixation test for a gonococcal infection carried out by Dr. Osmond gave a completely negative reaction, and I had no hesitation in saying that he was not suffering from gonorrhœa. On my advice, his wife was seen by Dr. Margaret Rorke, who reported that she could find absolutely no sign of gonorrhœa, and that the bacteriological tests strongly suggested a *B. coli* infection as the cause of the Bartholinian abscess.

You will realize that there were the makings of a marriage wreck in this history, and all from the assumption that a Bartholinian abscess spells gonorrhœa, from failure to make bacteriological tests of the abscess pus, or to examine other parts of the genito-urinary passages for confirmation of the suspicion.

In the course of a few years a specialist in venereal diseases meets a respectable number of cases in which mistakes in diagnosis have been made through failure to take even a little trouble over examination of the patient, and the consequences are often so distressing to the patient, so full of possibilities for wreckage of domestic happiness, that I thought it would not be a bad thing to make some of them the subject of a contribution to the proceedings of this Section. Fearing lest I should omit mention of some important errors, I asked my colleagues in the St. Thomas's Hospital Venereal Diseases Department to give me the benefit of their experiences in this matter, and I am indebted to them for some which I should probably have overlooked.

In questions of gonorrhœa it may sound surprising, but ordinary balanitis is sometimes diagnosed as gonorrhœa. I remember a case in which the mother of a boy at a public school was requested to remove him because the school doctor said he had gonorrhœa. He had simple balanitis. Dislike of examining the penis at close quarters must account for numbers of cases commonly seen in which a syphilitic chancre at the meatus or within the fossa navicularis has been diagnosed as gonorrhœa. It is quite a common thing to see cases of tertiary syphilis in which the patient denies any history of a sore, but admits gonorrhœa. I cannot help thinking that in a number of these, in which the patient says that the discharge was only slight and rather watery, the trouble was due to an intra-urethral chancre. The omission of a microscopical examination leads to many cases of urethritis which are due to chemical causes, to constitutional disturbance, or to infection with diphtheroids, staphylococci, *B. coli*, or organisms other than gonococci, being treated as gonorrhœa with potassium permanganate irrigations or with one of the fifty-odd preparations of silver which have been put on the market for this complaint. Sometimes a microscopical examination has been made, but only a simple stain has been employed, and a few streptococci inside pus cells have been diagnosed as gonococci. Sometimes a so-called Gram's stain has been used, but the violet has been dissolved out of

Gram-positive cocci by prolonged application of methylated spirit, and the process of conversion of Gram-positive cocci into seemingly Gram-negative ones has been completed by a prolonged application of such a stain as carbol-fuchsin.

On the female side vaginal discharges due to a multitude of causes other than gonococcal are commonly diagnosed as gonorrhœa. On the other hand, I have known scores of cases in which a woman who has clearly infected a patient has gone to a practitioner and been passed as free from gonorrhœa on the strength of one naked-eye examination, or at most a single microscopical test. It has forgotten that a cervical canal may be swarming with gonococci without a pus cell being present, or that gonococci may only intermittently come to the surface of the cervical canal, and that not one but many examinations are necessary to exclude gonorrhœa in a woman.

I have seen a number of cases in which the sudden appearance of a urethral discharge, due to the breaking open of a prostatic abscess which has formed quietly, has been diagnosed as gonorrhœa solely on the appearance of the discharge, or on badly stained microscopical specimens. Most of the cases have been in married men who, for one reason or another, had for some time suspended sexual intercourse. I imagine that their prostates had for years been secreting pus, but sexual intercourse had kept the foci draining. The micro-organisms have been in different cases staphylococci, *B. coli*, *B. lactis aerogenes*, *B. pyocyaneus*, *B. proteus*, and others, but not gonococci. One would think that in such a case common sense would dictate a microscopical examination of the pus; and, if the patient is married, as he often is, one might think it not a bad idea to make an inquiry as to the wife's condition before thrusting the patient into hell with a diagnosis of gonorrhœa. It may be worth mention here that a non-gonococcal prostatitis can cause symptoms which simulate typhoid, and I have known of some cases being treated for this disease even after the abscess has burst.

Epididymitis, especially if accompanied by a urethral discharge, seems often to write the word gonorrhœa in the practitioner's mind to the exclusion of every other possible diagnosis—for example, an infection with *B. coli*, or even *B. tuberculosis*. Yet only a few more minutes spent over the examination would serve to avoid the error if the case is not gonococcal. I have known some cases of right-sided gonococcal epididymitis diagnosed as appendicitis. The patient suddenly had an acute pain in his right iliac fossa, his temperature went up to 103° or 104° F., and perhaps he vomited. But his right rectus was not rigid, he did not look like an appendix case, and pressure on his cord as it crossed the ischio-pubic ramus caused very severe pain. By these signs, when I was in charge of a very large number of in-patients suffering from gonorrhœa, I saved quite a number of innocent appendices from removal and had none of general peritonitis.

In cases of arthritis, iritis, and similar troubles often classed as gonorrhœal, microscopical and cultural tests often fail to discover the gonococcus, and the complement fixation test with a gonococcal antigen is negative. On the other hand, my colleagues and I have seen a fair number of cases of gonococcal arthritis soaked with salicylates, or with potassium iodide, gonorrhœa not having been thought of, or having been excluded on the score of naked-eye examinations.

I owe much to the help of the microscope, to the culture tube containing a properly made medium, and to the complement fixation test. Properly used they save one from many pitfalls. They do not dispense with ordinary clinical tests, but to deny oneself their help is to walk blindfolded.

Turning now to cases of chronic gonorrhœa, I think the number of innocent prostates and seminal vesicles which have been massaged for trouble which a careful examination would have localized in the anterior urethra must be many thousands. Sometimes it is because in the textbook it says that prostatic massage will often clear up a chronic case of gonorrhœa, and so, without further

examination, the prostate is massaged. Sometimes a specimen of prostatic secretion is examined, but it has flowed along a urethra cleansed only partially with a stream of urine, not previously washed down by irrigation as it should be, and so the prostatic secretion contaminated with pus picked up in the urethra has been found to be pathological.

Omission of a urethroscopical examination leads often enough to months of treatment which a touch with a cautery point on one discharging follicle would clear up in a few days. Sometimes I have destroyed a small para-urethral canal and so ended a chronic urethritis which has kept a patient miserable for years.

Chronic urethritis is notoriously difficult to clear up, but I am certain that, if more pains were taken to examine and no method of examination omitted—microscopically, cultural, complement fixation, naked-eye inspection both outside and inside, as well as palpation with fingers and through the medium of instruments—inuch unhappiness of patients would be avoided. And a patient with a chronic urethritis is generally an unhappy man, far more so than one with a chronic catarrh of the nose or bronchi, and it is important to cure his urethritis, even though it may not be physically of any moment.

In questions of syphilitic infection, I would mention first the pernicious practice of commencing the treatment of early cases on mere suspicion—to give the patient the benefit of the doubt as is often said. Those who commence treatment on such principles without having verified the diagnosis by bacteriological methods cannot have much imagination of the effect of a diagnosis of syphilis on the patient's mind. Every syphilologist must have seen numbers of cases in which the patient gave a history of a genital sore which was not examined microscopically, and on the strength perhaps of what was called a weakly positive reaction, or even without any blood test at all, treatment was commenced. The history has left one with a very considerable doubt as to the correctness of the diagnosis, but in most cases one has not dared now to suspend the treatment because the negative reactions might be due to the treatment already given, even though this has been trivial. In some cases, however, I have been so convinced that the original diagnosis was wrong that I have suspended treatment. The reactions have remained negative, but the patient has not been freed of anxiety about his future; he has continued to be tested regularly, and when he has married, if one of his babies has snuffled a little, had a rash of any description, or any ailment whatever, he has worried over the possibility that I was wrong and that he had after all transmitted the disease to his offspring. The pitiable condition of his mind is due to the fault of the original man who commenced treatment to give him the benefit of the doubt. There need be no doubt. With bacteriological aids properly employed the diagnosis of an early case can be made with certainty, and, as a rule, rapidly. Promptitude in commencing the treatment of an early case is certainly important, but I am sure that it is not so important as certainty of diagnosis.

I have mentioned diagnosis on the strength of a serum reaction which is called "weakly positive." In the *Journal of the American Medical Association*, 1926 (Vol. 87, p. 1351), there appeared an article by J. H. Mitchell entitled "Menace of the slightly positive Wassermann reaction," with which I am entirely in sympathy. The author related cases in which a false diagnosis of syphilis had been made on the flimsy evidence of a weakly positive Wassermann reaction alone, or in conjunction with some non-specific dermatosis having a superficial resemblance to syphilis, such as pityriasis rosea or lichen ruber planus. The result had been the firm establishment of that intractable disease syphilophobia. Sometimes marriage engagements had been broken, and at others divorce proceedings been instituted, in consequence of a dishonest or an ill-trained practitioner founding a diagnosis of syphilis on such a reaction. I am sure that every syphilologist of standing could relate similar cases, and I am convinced that the term "weakly positive" should never be applied to any reaction which is weaker than the pathologist's standard for a diagnosis

of syphilis. I have always maintained that, for reactions which the pathologist considers insufficiently strong for a diagnosis of syphilis, the term "doubtful" should be employed, and if I got a report that a specimen gave a "weakly positive reaction," I should ask the pathologist if he meant by it such a reaction as is given only by syphilitic serums or one given sometimes by non-syphilitic.

A false diagnosis of syphilis is sometimes based on a single positive reaction with clinical signs which are only faintly suspicious. As an example I have in mind a patient I once saw who had been diagnosed as syphilitic on the strength of an ulcer on the lip and a single positive reaction. No *Sp. pallida* had been found in the secretion from the ulcer, there was no adenitis, and the whole history made a diagnosis of syphilis only the faintest possibility. The patient had attempted suicide after being told he was suffering from syphilis. Another specimen of serum was sent to be tested in the same laboratory and this time was reported as negative. I have always taught that, if a report that a serum reaction is positive is not supported by the clinical data, another specimen of blood should be sent. It is no disparagement of the care taken in laboratories to prevent errors to say that every now and again one will occur; specimens may be confused, a dose of complement may be omitted from a standard tube, a piece of cigarette ash may fall into a standard tube, or a number of other little things may happen which result in a normal serum being reported as positive. Such accidents do not happen once in a thousand tests, but, when they do happen, be sure it will be the specimen in which it is most important that no mistake should be made. If I have the least doubt of a result, I have another specimen tested.

As a good example of a mistake which can happen from jumping to conclusions from a naked-eye examination the following was related to me by my colleague Dr. Anwyl Davies. A person was sent to him with a diagnosis of primary sore on the penis and a secondary rash on the abdomen. Examination showed an oval ulcer on the glans penis with a tender inguinal gland. There was an erythematous rash on the abdomen below the umbilicus, and the combination might easily have been mistaken for syphilis. A prolonged search failed to discover *Sp. pallida* in the secretions, and close questioning revealed that in treating honeycombs with a chemical called "beemol," used to prevent Isle of Wight disease, some had dripped on to his waistcoat and passed through this to his skin. The subsequent history proved this to be the correct explanation of the lesions.

The mention of chemicals reminds one that a very fair imitation of a primary sore can be produced by self-applied caustic stick, and a burn of a lip by a cigarette has been diagnosed as a mucous patch. I once spent an afternoon on a medical board cleansing the record of an officer who had been diagnosed as syphilitic and had protested. The diagnosis had rested on what was said to be a mucous patch on the posterior pharyngeal wall. There was absolutely no evidence of syphilis, but there was a narrow stream of mucus stealing down the middle of the posterior pharyngeal wall, and with only a little book-learning for guidance one might have said it was a snail-track ulcer. Of other conditions in the throat Vincent's angina and diphtheria are, of course, common sources of error.

Scabietic runs on the glans penis are quite commonly diagnosed as primary chancres, especially if they have become a little crusted, and, on the other hand, a cervical chancre on the cervix is sometimes diagnosed as a gonorrhoeal erosion.

Warty conditions about the genitals are a great source of error. Numbers of cases of syphilitic condyloma have been treated for weeks with an ointment suitable for hæmorrhoids. Sometimes the patient has not even been examined, and the ointment has been prescribed on the patient's request for "something for piles." On the other hand, many warty conditions have been diagnosed as syphilitic because presumably they were warts, and syphilitic condylomata are warts. In most of these cases, apart from the fact that a careful examination is usually

sufficient to distinguish a syphilitic condition from a non-syphilitic, a microscopical examination of the serum from any early syphilitic lesion will usually settle the matter.

Perhaps a less serious error is to diagnose every syphilitic lesion on the genitals as a primary ulcer. It may be awkward then if the patient relates a history of syphilis a few years old and, the lesion being really a gumma, the serum reactions stubbornly remain positive.

Extragenital chancres are commonly overlooked. I have known of a tonsil which was the seat of a chancre being emulsated and the same patient being sent later to a fever hospital for German measles, the true diagnosis being reached only when the eruption did not clear up in the time usual for measles. Chancres of a terminal phalanx are usually diagnosed as whitlow until a rash appears. The worst error of this kind I ever saw was in a medical officer who was looking after syphilis cases during the war. He allowed his finger to be treated for whitlow, and his tonsils to be cauterized for ulcers, and then went peacefully to hospital for measles. It dawned on him that he had accidentally contracted syphilis, when the measles rash was succeeded by a profuse papular syphilide.

A common mistake is to assume that in a patient with positive serum reactions all abnormalities are themselves syphilitic.

Tertiary syphilis of the tongue has led to many epitheliomata there being overlooked, and I would caution against being misled by a temporary improvement following administration of arsenobenzene preparations in these cases. The tendency to regard all lesions on the genitals as venereal in origin sometimes leads to an epithelioma of the penis being diagnosed as gumma.

Gummata of the testicle have fairly often been removed under a diagnosis of new growth. In one case which I remember I feel sure that the practitioner and also the pathologist were misled by the blameless life of the patient, and it was not until many months later, when an undoubted gumma occurred elsewhere, that the blood was tested.

I think the tendency in nervous diseases is to think of syphilis and in cardio-vascular disease to forget it. At least quite a number of cases of nervous disease due to causes other than syphilis have been sent to me for treatment, and I have seen a fair number of cases of syphilitic myocarditis in which I wished my predecessors had thought of syphilis earlier and left me with less of a wreck to treat.

In questions of treatment it is always a source of wonder to me that there are so many people who give only partial treatment if there has been a doubt about the diagnosis. They would probably agree at once that a thing cannot both be and not be, but yet they act as if it could.

In patients under antisiphilitic treatment failure to diagnose certain skin rashes as due to arsenic and continuance of the treatment has led to most tragic results; so much so that one would emphasize with all one's strength the advice to take serious notice of any dermatosis in a patient undergoing arsenobenzene treatment, however trivial the skin affection may seem. One should consider most seriously whether or not this is arsenical, and decide on continuance of this form of treatment only on firm conviction that it is not. Otherwise the result may be a dermatitis from which the patient may die, or recover only after a long and trying illness. I ought to mention here that bismuth sometimes causes a troublesome dermatitis, though it is very uncommonly so acute as can be one due to arsenobenzene.

I have thus attempted to set out some of the commoner errors in diagnosis in questions of venereal disease. The subject could be expanded to far greater length, but even if space would permit of this the result would only emphasize still more the principle, that, in venereal diseases as in others, one must look for and gather all the evidence which will bear on the diagnosis. And, having gathered the evidence, one must sift it with judgment and common sense. If this discussion leads to some reduction in the wretched victims of wrong diagnoses—the poor devils who go through life under the

shadow of an anxiety for which there is no real reason—it will have done some good.

Observations of the Cause and Prevention of Influenza and Influenzal Pneumonia.

By E. C. ROSENOW.

(Abstracted from *International Medical Digest*, Vol. XV, July, 1929, No. 1, p. 15.)

THE author suggests the following hypotheses regarding the *Bacillus influenzae*:—

Peculiar strains of these organisms occurring individually or symbiotically should be considered the cause of the varied manifestations of influenza. Mutation or "dissociation" in the pneumococcus-streptococcus group normally present in the upper respiratory tract in human beings, sudden acquirement of exalted and peculiar virulence, especially of the streptococcus group, and hypersensitiveness or allergy to the bacterial proteins, should be considered as important factors in the production of the peculiar manifestations of this disease.

He had previously stated that:

"The freshly isolated strains from influenza and its accompanying lesions have been found to produce relatively large amounts of 'anaphylatoxin' both *in vitro* and *in vivo*. The idea that the virulence of these bacteria may depend in part on their ability to produce 'anaphylatoxin' is in accord with my previous finding that virulent pneumococci and their filtrates produce a larger amount of this toxic substance than virulent pneumococci. The picture in animals is clearly that of an anaphylactic intoxication, and suggests that the symptoms and lesions in man as recorded by numerous observers may likewise be due to this cause in which sensitization of the host to the bacterial proteins may or may not play a part. Findings as follows indicate this mechanism:

1. The delay in the coagulation time of the blood, leucopenia and cyanosis.
2. The marked tendency to develop acute pulmonary oedema with a distended lung and relatively immobile expanded chest and extreme respiratory effort.
3. The voluminous lung as found at necropsy.
4. The occurrence of the rupture of alveoli and consequent subcutaneous emphysema (bronchial spasm).
5. The frequency of abortion (contraction of unstriped muscle) and other uterine disturbances.

"The small anaerobic organism isolated from filtrates by Olitsky and Gates in the early stages of influenza should be regarded as being related to the streptococcus-pneumococcus group. They have shown that after long cultivation the organism becomes less anaerobic, of larger size, and of fairly typical streptococcal morphology."

While common-sense measures of quarantine are indicated in epidemics, the disease cannot adequately be controlled in this way. The author recommends that a concerted effort on a large scale be made against this disease by means of vaccines prepared from freshly isolated strains in proportions approximating the bacterial flora in different localities.

The method of preparation is as follows:

The bacteria are grown in gallon bottles of broth; this is clarified and the bacteria then are stored in dense suspension in glycerin and sodium chloride solution. The vaccine is made by diluting these dense suspensions with sufficient sterile sodium chloride solution. These dilutions are heated at 70°C. for one hour and 0.3 per cent. phenol is added as a preservative. One cubic centimetre is made to contain 5,000,000,000 killed bacteria. Three subcutaneous injections of 0.3, 0.5 and 1 c.c., respectively, are given at weekly intervals, and then a monthly injection of 1 c.c. for as long a time as needed. The dosage for children should be about half, and for infants about a fourth that for adults.

Stammering in Women.

(Abstracted from *The Medical Press*, September 25th, 1929, p. 247.)

SEVERAL writers to *The Times* have remarked upon the preponderating number of stammerers in the male sex, the proportion of male to female stammerers being about five to one.

Be the explanation what it may, girls and women are much more glib of tongue than boys and men. One notices this difference especially in comparing the speech of little girls and boys. Little girls overcome the difficulties of enunciating consonants more readily than boys—and stammering pertains, of course, to the consonants. We are apt to lose sight of the complexity and delicacy of muscular co-ordination needful for the enunciation of the consonants. One of the most difficult is the *th*. The *h* of the *th*, not being pronounced in the German language, has of recent years been (wisely, I suppose) omitted, so that *That* is now written *Tat*, and *Their*, *Tier* (which, etymologically speaking, is to be regretted).

It is remarkable that, unless a foreign language is taught before adolescence is completed, the student rarely learns to pronounce it correctly: the nerve centres engaged in articulation tend to lose their plasticity after adolescence.

Spectacles and their Origin.

(Abstracted from *The Medical Press*, September 18th, 1929, p. 229.)

THE 300th anniversary of the grant of a charter to the Company of Spectacle-makers has been the occasion of a congress and exhibition in London. The identity of the actual inventor of spectacles is uncertain, but there are grounds for attributing priority to Salvina d'Armato, the inscription on whose tomb at Florence, which is dated 1317, describes him as the inventor. Roger Bacon and others are similarly credited with the honour, and there is doubt whether spectacles were not known to the ancient civilizations of the East. The use of lenses for reading and other purposes was doubtless employed by the monks in mediæval times, and there is a fresco at Treviso which was painted in 1352, in which eye-glasses are depicted. From one single lens there evolved in time the pair of spectacles with side-pieces to keep them in position, and the curved bridge to support them on the nose, the mounts varying from leather to metal strips which passed round or over the top of the head. The Chinese used cords fixed to the glasses and carried over the ears, to be held in position by weights at the ends. Not until the eighteenth century do hinged side-pieces appear. The development and use of spectacles were forwarded by the invention of printing and the revival of learning in the fifteenth century, following which guilds of spectacle makers arose in Italy, Germany, France, and probably England, though the account of any such guild before its incorporation disappeared in the Great Fire. In earlier times spectacles were peddled by vagrant craftsmen such as is depicted in Ostade's picture of "The Spectacle Maker," who appears with his basket offering to the purchaser a pair which "suited" the vision of his customer. In 1804, a pair of spectacles could be obtained for three shillings and sixpence; in 1846, pince-nez came into fashion as a refinement of their predecessors, the lorgnettes. Examples of lenses of quartz or pebbles, of coloured glasses used for protection from glare, of Helmholtz's ophthalmoscope, and of Marshall's lenses are exhibited in the museum of the British Optical Association and Science Museum. There also may be seen Divini's compound microscope, Hooke's microscope of 1665, and Marshall's compound microscope of 1693, which was described a few years later as having been invented for "viewing the circulation of the blood." The invention of the microscope is generally credited to Jansen, in the sixteenth century, and that of the telescope to Gianbattista della Porta. Newton was the first to use a reflecting

telescope, and a terrestrial telescope made by Christopher Cook in 1673 is still preserved.

Essay Review.

REPORT OF THE BENGAL FIELD MALARIA RESEARCH LABORATORY AT KRISHNAGAR FOR THE YEARS 1926 TO 1928. BY S. N. SUR AND P. SUR, CALCUTTA, BENGAL GOVERNMENT PRESS, 1929.

IN a review of the work of the Sonarpur Malaria Observatory in this journal (Vol. LXIII (6), 1928) the writer expressed regret that this station had been practically closed down for the last three years, but the present report shows that it was only closed down to be immediately reopened elsewhere in the Province. As with the earlier report, the present one is simply packed with invaluable information, and it is much to be regretted that in spite of the recent editorial in this journal about the occlusion of work of this nature in Local Government papers, the present report is again marked "for official use only."

The chief problem studied was the species of *Anopheles* causative of malaria in the Central Bengal district in which the new laboratory was located. As the sketch map shows, the area chosen was admirable, for a short journey enabled villages with 100 per cent. and 9 per cent. spleen rates to be compared in regard to their anopheline population.

The anophelines incriminated are the three species of the *fuliginosus* group, which Dr. Strickland and the writer have both been able to neglect in other parts of India. With proper scientific caution the authors of the report close with the following:—"We must not conclude that the observations we have made in Krishnagar. . . . will be true for other districts. . . . Every district may have got its own fauna of mosquitoes and their special peculiarity of prevalence and habits." Strickland's working hypothesis of "once a carrier, always a carrier," is *vis-à-vis* the results of the Drs. Sur and his and my own, shown to be very dangerous, and those of us who have to found controls on brief surveys may well envy the opportunities which the Drs. Sur have so well made use of, to remain in one spot studying one problem for 2½ years.

Chart 3 of the report shows that humidity and temperature (if Jancsó's work be directly applicable to India) are favourable to transmission throughout the year. There is a sharp drop in temperature from October to March, with a minimum in January, and a sharp drop in relative humidity from January to April, with a minimum in March, but Table I, dealing with the sporozoite rate of the *fuliginosus* group, shows that not only are sporozoites found from August to December, as one would expect, but, in both winter seasons in which work was in progress,

after a negative January, there was a positive February rate higher than any monthly rate in the malaria season. From Table III, where the three species of this group are listed separately for sporozoite rate, we see that the infections at this season are all in true *fuliginosus*, but apparently the other two species are very rare at this time of year. This Table III shows that in the malaria season, the last third of the year, it is *philippinensis* that is the carrier. Only once, in 15 months' dissections, was *A. pallidus* found infected, three specimens in October 1927, thus confirming the general acceptance of this species as of no practical importance.

When, however (Table IV), we come to artificial infections, we find *pallidus* to have a higher rate than *fuliginosus*, whilst *philippinensis* were all negative, but this last, we think, can be attributed solely to the small number available for experiment, nothing less than a 14 per cent. rate (higher than either of the others) could have been expected to yield a positive finding.

We have then to study the positive February findings in *fuliginosus*. Such should show themselves by an increased incidence of new cases of malaria in March (Table II), but this is not seen to occur. As sporozoites cannot be specifically differentiated, can it be that in winter *fuliginosus* is showing the result of the operation of "Jansco values" for some (?) bird *Plasmodium*, and that the infections found are not with any of the human species? For (Chart I), though in both years the number of breeding places is approaching its minimum in February, yet (Table Va), it is at its percentage maximum in human dwelling houses in this month, and (Table Vb), at its percentage maximum, or near it, in cattle sheds. Neither are the actual numbers in both houses and cattle sheds in the month insignificant, for, by calculation from these tables, we find the following comparisons:—

	February.		November.*	
	Houses,	Cattle sheds.	Houses.	Cattle sheds.
1927	.. 224	716	341	263
1928	.. 282	80	740	325

There is therefore no apparent reason why in February there should not be a malaria incidence almost equal to that of the earlier months of winter, the more so as it has already been shown that the percentage infected is higher in February than in any other month. If these sporozoites are of human species, then some completely unenvisioned factor precludes them from causing infection.

With all due deference to the conclusions of the authors that the carriers of the Nadia District are the anophelines of this group, may we direct their attention to the following table, made up

from their Tables Va and XI, in connection with *A. minimus*?

1927.	Caught in houses (actuals).	Percentage of new cases malaria.
January	.. 0	3.6
February	.. 0	2.6
March	.. 2	2.5
April	.. 2	1.7
May	.. 1	2.0
June	.. 0	2.0
July	.. 2	2.8
August	.. 6	4.0
September	.. 11	4.7
October	.. 27	13.3
November	.. 11	31.0
December	.. 11	29.5

May not the sharp rise in *minimus*, not a species which remains in houses after biting, according to Carter and Jacocks, in September, start the annual epidemic, which is then kept up by the enormous numbers of the much less susceptible *fuliginosus* group thereafter? But Chart 6 shows how closely *fuliginosus* is correlated with fever. The incidence of *culicifacies* in houses, save in the first three months of 1927, over the whole of the rest of the two years, is so insignificant that this species can have nothing whatever to do with malaria at Krishnagar.

Table Vc gives interesting comparisons between the preference for human and bovine blood in the different species. From this we see that thrice as many *rossi-vagus* are found in houses as in cattle sheds, whilst the *fuliginosus* group has an over 50 per cent., *A. pseudojamesi* thrice, and *A. sinensis* 250 per cent. preference for cattle over men.

Tables VIII and IX give interesting details of breeding prevalence by larval catches by species in each month, from which we see *rossi-vagus* with a May to July maximum, the *fuliginosus* group in September, *minimus* in November, *culicifacies* in April, *sinensis* about December, whilst *barbirostris* varies from October to January. In Table IXa we get two villages with low spleen rates compared with one with an 80 per cent. rate. The overwhelming prevalence of the *rossi* group in the two former is well brought out.

Table X gives some details of survival rates, species by species and month by month. This is of extreme importance. Survival over 11 days, even in the most favourable period for transmission, is probably essential for infectivity to develop. But the table would have been infinitely more valuable if the monthly percentage by species had been worked out, instead of all species by the month. The general rate for *fuliginosus*, *sinensis* and *rossi* is shown to be 67, 51 and 23 respectively, but owing to differing number of different species having been experimented with, the table as it stands is not of as much value as it might be, and we have recast it as follows:—

* Month preceding maximum new case incidence of year.

Percentage surviving 11 days and over.

	<i>fuliginosus.</i>	<i>sinensis.</i>	<i>rossi.</i>
January ..	97	60	39
February ..	76	67	33
March ..	67	20	14
April ..	50	..	12
May ..	67	..	22
June ..	80	..	44
July ..	60	..	0
August ..	28	0	10
September ..	66	17	17
October ..	67	40	38
November ..	63	70	28
December ..	69	71	25
AVERAGE ..	67	51	23

Anyone interested, from this table with Table Va can work out the number of specimens of these three species at least that were alive in the house catches each month with a greater age than 11 days, and then proceed to correlate with new infections, from Table XI, so far as mosquitoes protected can be compared with mosquitoes free. But in the rains free mosquitoes are at risk from wind and rain in their ovipositing journeys, whilst nothing is known of the seasonal activities or prevalence of hunting spiders, geckos, etc., but the work here recorded suggests lines of research which are completely untouched.

After 18 pages devoted to the above details, the parasite incidence is next recorded: 1,055 positive slides over two years (55 per cent. + ve) give total species distributions of *P. vivax* 24.6 per cent.; *P. malariae*, 14.3 per cent.; *P. falciparum* 41.2 per cent.; mixed 19.8 per cent. Most unfortunately no details of the mixed infections are given. By months we see *vivax* maxima in April to May and August to September, *malariae* maxima in March and May (not in winter), and *falciparum* maxima at the end of the year and into January. The mixed infections are very high in winter, but much of the value of this work is lost by the non-recording of details of the mixed infections. Similarly the gametocyte figures, which would have been absolutely invaluable, are spoiled by similar lack of recording. We would urge the authors to republish Tables XII, XIIa, and XIII with details of mixed infections.

Seasonal variations in the spleen index are next discussed. Two villages showed big fluctuations in the crude rate, but the 100 per cent. village Jatrapur remained at this figure throughout. The fluctuations were seasonal. One-finger spleens disappear in the epidemic and post-epidemic seasons, whilst the "beyond umbilicus" group varies inversely with them.

We would again most heartily congratulate Drs. S. N. and P. Sur, and their Chief, Dr. Bentley, on the work that has been carried out. We have heard a cry about the indifference of Government to the decimation of Bengal by malaria. The years of work at Sonarpur and

Krishnagar, all, be it noted, carried out by Indians, effectively give the lie to these political cries. When, in a sober moment, Bengal takes stock of its public benefactors, S. N. Sur, P. Sur and M. O. T. Iyengar will be remembered long after C. R. Das, Subas Bose, and other political agitators have sunk with Perkin Warbeck into the limbo of historical curiosities.

R. SENIOR-WHITE.

Reviews.

A DICTIONARY OF SCIENTIFIC TERMS.—By I. F. Henderson, M.A. and W. D. Henderson, M.A., B.Sc., Ph.D., F.R.S.E. Second edition. Edinburgh: Oliver & Boyd. Pp. 352. Price, 16s.

THIS is an excellent and much needed book, and a copy of it should be in every scientific library in India. It includes in all some 10,000 terms used in biology, anatomy, botany, zoology, embryology, cytology, physiology, bacteriology, and palæontology. For each word the derivation is given, in most cases of course from either Greek or Latin, and for the sake of simplicity the Greek words are transliterated into the Roman alphabet.

In the second edition some 1,500 new terms have been included and the whole re-set. Both the authors and the publishers have done their work very well, and the volume will be of real value to workers in many different branches of science, and not least to medical research workers.

R. K.

STARLING'S PRINCIPLES OF HUMAN PHYSIOLOGY.—By C. Lovatt Evans, D.Sc., F.R.C.P., F.R.S. Fifth Edition. London: J. & A. E. Churchill, 1930. Pp. XV plus 1039 with 543 illustrations, 9 in colour. Price, 21s. net.

THE fifth edition of Starling's *Principles of Human Physiology* will be welcome to all students and teachers of the subject. Physiology has advanced with such rapid strides during the last few years that a new edition of the book embodying all the recent advances was urgently called for, and this has been produced by Professor Lovatt Evans. It is indeed pleasing to note that the present edition fully maintains the place of honour which has so long been held by this book.

The subject-matter has been thoroughly re-adjusted and the whole chapter on the central nervous system has been re-written by Professor Hartridge. All the new researches on vitamins, endocrines, reticulo-endothelial system, etc., have been incorporated without increasing the bulk of the book. Many new diagrams have been added and some of the older ones replaced by new ones. The printing and format are excellent and there cannot be any hesitation in recommending the book to students as well as to general practitioners.

R. N. C.

BEAUTIFUL FLOWERS OF KASHMIR. VOL. II.—By Ethelbert Blatter, S.J., Ph.D., F.L.S. Illustrated by Mrs. G. A. Wathen, and Haldar Joo Wall. London: John Bale, Sons and Danielsson, Ltd. Price XV plus 204. Price, 21s. or Rs. 15-12 net.

THIS volume is likely to make a strong appeal to the minds of all those who are artistically inclined. The book is rich in exquisite tricolour pictures of plants and flowers which cannot fail to be appreciated by those who are interested in the flora of Kashmir—the Garden of Eden of India. The botanists will also find enough food in the various chapters—the habitat of the plants, their characteristics in relation to altitude and environment, the season for flowering, etc., are all very useful information for them. The derivations and meaning

of the different botanical names, the glossary and the index of popular names will be very helpful to readers. It is a pity that the medicinal properties of these plants and flowers could not be dealt with for want of space—this feature would have made the volume still more acceptable to the medical men.

R. N. C.

MAN'S PLACE AMONG THE MAMMALS.—By F. Wood Jones, F.R.S. London: Edwin Arnold & Co., 1929. Pp. VII plus 372. Price, £1-1-0.

THIS is a contentious work, which traverses debatable ground throughout, and, to any reader not in the full swing of the current of up-to-date mammalian systematics, presents ideas considerably at variance with the accepted zoology of his student days. The subject, however, is presented to us so fully and explicitly that the plain biologist and medical man can follow the argument without masses of previous collected reading, and the argument throughout appears convincing, though we have no doubt that it will be fiercely attacked by the author's fellow specialists who hold divergent views. To the ordinary non-specialist scientific reader it will give a much clearer concept of much modern research that, if he sees it at all, he sees in detached special articles in such publications as *Nature*; and, though by no means light reading, the book is so full of fascinating information that it forms a welcome change from one's own special line of study.

The book opens with a chapter on "the need for a review of the question of human phylogeny," from which we quote the following:—".....it is wellnigh impossible to obtain a satisfactory insight into the details of accepted beliefs, unless some regard is paid to the sequence in which theories have been accepted and dogmas become current." This consideration naturally leads on to two chapters on pre-Darwinian and Darwinian biological thought, in the latter of which it is shown that what passes for Darwinism to-day (and not all of us have read *The Origin* in detail) is coloured by the later views of Haeckel, Huxley, etc., and is far more dogmatic than the original statements of the great biologist himself. The next chapter deals with a study of function in regard to structure, and is followed, in support, by a brief chapter on some of the recent work in experimental embryology—a closed book to most workers, and another on the inheritance of acquired characters, that is too condensed and contentious. The next chapter, on "convergence," is too condensed for anyone who has not studied the delightful book by Willey, but sets out further cases not touched on by that writer which are germane to the present thesis. This opening portion of the book concludes with three chapters on "Man's place in Nature" before, during, and after the Darwinian period. Having digested the 67 pages just summarized, the reader is presumed to be sufficiently up-to-date to tackle the main thesis.

Now comes the shock. In some 75 pages the author shows, and shows very clearly, that the *Lemuroides* are not precursors of the monkeys, but are the shrews (*Trpoides*) modified by convergence to superficially resemble the *Pithecoidea*, which have, at the base of their phylogenetic tree, that "living fossil" *Tarsius*. A detailed account of what is known of this rare wild animal is followed by accounts of the New and Old World monkeys, showing how they probably arose separately from fossil Tarsioid stocks, and that the Old World monkeys and Anthropoids themselves diverged very early from a common ancestor. This thesis occupies another 150 pages. The final 70 are occupied with Man, and the author stamps ruthlessly on "missing links" and anthropoid characters in *Homo*, and derives that genus as a direct branch from a Tarsioid ancestor. The case made out is certainly at least a good one.

With expert palaeontological knowledge, the author tears down the faith that has been put in some of the fossil remains of recent discovery. We are so apt to see a tooth or a jaw bone given an important generic and specific name that we are inclined to think as if the entire skeleton of the animal were known. We can see

the author being fiercely attacked by specialists, but to the plain biologist his arguments are extremely convincing.

The chapters on skeletal and internal structure, and on habits of all the species discussed, are extremely interesting and valuable, whilst the book is illustrated by an excellent series of photographs of the animals themselves, in addition to very numerous text figures. Our immediate progenitor, *Tarsius*, in Plate III, Fig. 1, was such a jolly little beast that no one need feel distressed at having him, instead of the gorilla, at the top of their family tree!

R. S. W.

FABLES AND SATIRES.—By Sir Ronald Ross, K.C.B., K.C.M.G., F.R.S. London: Harrison and Sons, Ltd. Pp. III plus 71. Price, 7s. 6d. net.

ALTHOUGH most of us have been taught early to conceal from the world's gaze that minute part of our inner selves which we know to be singular, the dullest can bring into the public market, if he will, one unique thing, one commodity new and surely interesting, himself.

The psychologists nowadays are beginning slowly to show us how harmful a practice is repression, and here is one, a great scientist, who by his perseverance and hard common sense has given untold benefits to millions of his fellow men, wise enough to offer to the world that precious residue of himself that was left over from the day's toil, a residue which lesser men discard, if ever they recognize its worth, but which he in his wisdom preserved.

Sir Ronald Ross has done well to publish these verses, and among them will be found nothing that can be confused with the work of that School of Poetry which, largely by its self-advertisement, has been so conspicuous since the outbreak of the Great War.

As a poet he belongs assuredly to the right wing, and to-day his verse might be called reactionary, and this is very far from being a slur. He may not possess "that large utterance of the early gods," but he is not obsessed with the state of his own nerves, nor does he look on the writing of verse as an exercise in introspection. It is not his delight to veil meaning in an insipid mist of deliberately perverted words, nor to sacrifice his clarity of communication to a syncopated rhythm that can be distinguished by the writer alone, and which, if one is bold enough to attempt it, will convey only a headache to the reader.

In spite of several instances of the printed word being tortured into a shape unnatural and unnecessary, he tries to give words their right uses, and that by itself will earn the gratitude of lovers of the English language. It is not the part of a critic only to find fault; a far more worthy asset is to be capable of recognizing sincerity in the writings of others, and here, in these verses, certain technical weaknesses may be forgotten in the originality of the poet's themes, his sudden flashes of wit, and the obvious feeling that inspired their birth. The book is worth reading, and worth keeping, not so much because it is especially remarkable in single pages, which is why no quotations are given, as because by its help we can reach out and come into touch with a charming personality, and follow a great scientist and a great benefactor when, wearied with the chase of the wily Anopheles, he turns to the pursuit of the equally elusive anapest.

THE PRACTICAL MEDICINE SERIES, 1928.—Edited by G. H. Weaver, M.D., L. Brown, M.D., and others. Chicago: The Year Book Publishers. 1928. Pp. 832. Price, \$ 3.00 net.

"THE Practical Medicine Series," comprises eight volumes on the year's progress in medicine and surgery. *General Medicine* by H. Weaver, L. Brown, G. Minot, W. Castle, W. Strond and R. Brown of the 1928 series, and published by The Year Book Publishers of Chicago, is one volume of the series. This volume consists of five parts dealing with the infectious diseases prevalent in

America in Part I, diseases of the chest in Part II, diseases of the blood, hamopoietic system and kidney in Part III, diseases of the heart and blood vessels in Part IV, and diseases of the gastro-intestinal system and metabolism in Part V. The book is handy and contains all the necessary information in connection with the treatment of all the important diseases that prevail in America. In some cases the various therapeutic measures are very well discussed. The book will be useful to medical practitioners.

S. P. B.

METHODS AND PROBLEMS OF MEDICAL EDUCATION. THIRTEENTH SERIES. VANDERBILT UNIVERSITY SCHOOL OF MEDICINE, NASHVILLE, TENNESSEE.—Pp. 130. Profusely illustrated. New York, The Rockefeller Foundation.

EVERY Dean, if not every Professor, of a medical school or college in India should be interested in this wonderful and very valuable series of publications. The Rockefeller Foundation have made a splendid contribution to the cause of medical education by their issue, for they consist of brief and fully illustrated accounts of different clinics, medical schools and colleges, laboratories, and methods of teaching from different parts of the world. The articles on different departments are written by the men in charge of them, and illustrated by photographs. The complete series thus comprises a set of volumes comparing present-day methods of teaching, investigation, and research in many different countries.

The present—thirteenth—series deals with the Vanderbilt University School of Medicine, and opens with a general account of this school by Dr. G. Canby Robinson and an aeroplane view of the buildings. Vanderbilt University was founded in 1873 as the result of a grant of a sum of one million dollars by Cornelius Vanderbilt, but the medical school was in financial difficulties until Mr. Andrew Carnegie and the General Education Board came forward with financial assistance in 1913–1919. Finally a new hospital and medical school was built in 1925, and the entire department reorganized.

The chief interest of this lavishly illustrated memoir is that it presents a detailed account of a completely up-to-date American medical school intended for thorough medical education of a small number of students. The professor at an Indian medical college, who has to deal with hundreds of students annually, may well envy the professors at Vanderbilt University, where the number of students is limited to 50, and there are 208 beds in all in the different wards. What is aimed at here is thorough education of selected men, not mass production of "doctors," as in India. And the photographs of the different departments show how thoroughly this plan is adhered to. The medical curriculum follows that usually in vogue, though a special feature is that third year students are assigned to the various wards in groups so as to gain a thorough training in methods of examining patients, before they are told off in their fourth year to different divisions of the out-patient department.

Successive chapters in the volume deal with the organization, planning, and work of the different departments; library, anatomy, biochemistry, physiology, bacteriology, pathology, medicine, pediatrics, surgery, obstetrics, etc., and the school of nursing. A novel and very interesting departure is a central apparatus shop for the whole school for the repair of instruments, microscopes, apparatus, etc., an innovation much needed in medical colleges in India. The library is designed to hold 35,000 volumes, and takes in 284 current medical periodicals; it also has separate reading and work rooms. In connection with the anatomy department special courses are given in histology and neurology; there is also a special tissue-culture room. The biochemistry department is a model of what it should be, and will interest every laboratory director in India; it includes a constant temperature room. In all the departments separate laboratories are provided for routine, teaching, and research work, and the "unit" system is largely followed, one and two-unit laboratories being provided.

Throughout the volume detailed plans of the different departments and laboratories are given. The research

department of the pharmacology section consists of twelve rooms, and is obviously very spacious. The section of preventive medicine has a special research laboratory for parasitology. The clinical laboratories adjoining the wards appear to be spacious—an essential only too often forgotten by architects when designing hospitals. Pediatrics is given a separate department to itself. The surgical section has a separate instrument room, also laboratories for work in experimental surgery, and a technician's room. Finally a separate School of Nursing trains nurses and grants a degree in nursing.

The professor at any Indian medical college may well study this brochure with interest. We would also commend it to the Finance Departments of the different Indian provinces. This is what is considered suitable provision for fifty medical students in a new and up-to-date medical school in America.

A limited number of copies of the volumes in this series are available on application to The Rockefeller Foundation, 61, Broadway, New York, N.Y., and if any dean of a medical school or college in India is having trouble with his local Finance Department, we would advise him to study the series.

Finally, we must recognize the great value of the publication of this series of brochures by the Rockefeller Foundation, for the result must be to further the cause of medical education and research work by the collation of information with regard to buildings, equipment, and methods.

R. K.

SLEEP AND THE TREATMENT OF ITS DISORDERS.

—By R. D. Gillespie, M.D., M.R.C.P., D.T.M.
London: Baillière, Tindall and Cox. 1929. Pp. IX plus 267 with 5 figures in the text. Price, 7s. 6d. net.

IN this small volume the author has tried to give a concise and a clear account of the various phenomena associated with sleep, without going into controversial details. The book opens with a general survey of the normal physiological phenomena of sleep. Then follows a comprehensive description of the various effects of insomnia and of the types of disorders associated with sleeplessness, all views being based upon experimental and clinical observation. The author then gives in detail the methods which can be employed to combat these disorders and discusses the rationale on which they are based. The pharmacology and therapeutics of the hypnotics are briefly discussed, and the methods employed are classified according to the different types of sleeplessness. The volume is admirably adapted to serve as a book of reference to the general practitioner in dealing with a most troublesome symptom.

R. N. C.

INDIAN THERAPEUTICS FOR MEDICAL STUDENTS AND PRACTITIONERS.—By D. V. Sandu, G.P.A.S. (Bom.), L.M.S., etc. Second Edition (Revised and Enlarged) Bombay: D. K. Sandu Bros. 1928. Pp. VII plus 147. Price 7 annas. Foreign 1s. 6d. net.

Indian Therapeutics by Dr. D. V. Sandu is an attempt to present the main facts of Ayurveda on the lines of Western medicine. At the very outset, the "Tridosha Theory"—the foundation on which the whole superstructure of Ayurvedic system rests—has been discussed and the author tries to explain it in views of the modern scientific discoveries. Various drug-combinations and Ayurvedic formulæ are incorporated in the body of the book and it is expected that these will be of some use to junior practitioners of the indigenous system. The chapters on dietetics and vitamins are interesting and have been written entirely from the modern European point of view. The book is full of misprints and typographical errors and the general get-up is very poor. It appears to be too elementary for medical practitioners and the utility of the book is doubtful.

R. N. C.

A DIET SUMMARY IN AVERAGE SERVINGS FOR DIABETICS AND OTHERS SUFFERING FROM DISORDERS OF METABOLISM.—By P. J. Cammidge. London: Baillière, Tindall and Cox. Pp. 8. Price, 1s. net. (6s. per dozen).

THE system of dieting adopted by the author in this brochure appears to be suitable and easy for the average diabetic patient to carry out.

The author has given 4 tables:—

"A" which is predominantly protein, and "B" which is predominantly carbohydrate, in composition; "C" is mainly fat, and "D" contains a good mixture of the various nutritive principles. Each of these tables is further subdivided into "groups" according to the amount of protein, carbohydrate or fat it contains in an "average serving." An arbitrary unit has been adopted, such as 1 protein-ration (P. R.) which means 20 grams of protein; 1 carbohydrate-ration (C. R.) equals to 4 grams of carbohydrates; and 1 fat-ration (F. R.) means 5 grams of fat. Thus, according to the quantity (in grams) of protein, carbohydrate, and fat allowed to the patient, he can make a selection of his diet by the use of these tables.

In our opinion the tables are simple and practical, and will be found useful in breaking the monotony of the average diet of diabetic patients.

J. P. B.

Annual Report.

PUBLIC HEALTH ADMINISTRATION OF THE PUNJAB FOR THE YEAR 1928. BY LIEUT.-COL. C. A. GILL, D.P.H., I.M.S., DIRECTOR OF PUBLIC HEALTH, PUNJAB. LAHORE. SUPERINTENDENT, GOVERNMENT PRINTING, PUNJAB, 1929. PRICE RS. 3-12-0.

COLONEL GILL's report for 1928 is of special interest in showing that, in spite of unusual vagaries of climate, the year achieved the distinction of being the healthiest ever recorded in the history of the Province. There were unusually severe dust storms in March, which were responsible for a partial failure of the wheat crop; an unusually hot and dry May; a prolonged break in the rains from 23rd July to the last week in August, and excess of rainfall in September. As a result the prices of wheat and barley were slightly above normal, though the prices of food grains of less value were normal or below normal. On the other hand, the low winter rainfall was unfavourable to plague, and the autumn was healthier than usual.

The estimated population at the end of the year was 22,285,553, and the increase in population during the year—442,696, is the highest figure ever recorded for the Province. The Province, however, can absorb even an abnormal increase in population for several years to come, in view of the extension of canal irrigation and the formation of new canal colonies. A serious feature of the position, however, is the excess of males over females; this calls urgently for an extension of the very considerable volume of maternity and child-welfare work which is already carried out in the Province.

The provincial death rate was 21.58 per mille, and the birth rate 46.30, the difference between the figures, 21.58 per mille, being the highest such figure on record for the Punjab. The unusual healthiness of the year is to be attributed chiefly to the low incidence of plague and of malaria. Infant mortality was also unusually low, 167.62 per mille, as compared with the quinquennial average of 193.57. As is well known, the Punjab heads the list of the Indian provinces in the birth rate and natural increase of population. The rise in the birth rate was conspicuous in all parts of the Province, and is attributed to the absence of malaria in epidemic form. The mortality from malaria and plague was unusually low. As is usual in years when

great epidemics of these diseases are absent, the urban death rate, 26.92, exceeded the rural death rate, 24.46. As usual, the death rate was highest at the extremes of life, in infancy and in old age. As a community, Hindus appear to be slightly more susceptible to disease than do Mahomedans.

It has hitherto been impossible to entrust the work of registration of vital statistics to the district medical officers of health, as these officials have not yet been provided with the necessary clerical staff. Revised forms for the registration of births and deaths in rural areas were introduced in April, 1928. Entries checked in birth registers during the year numbered 778,372, and deaths, 459,048; but the fines inflicted on defaulters are so trivial that they tend to defeat the purpose for which they were inflicted.

Turning to the principal diseases, *cholera* was responsible for 2,034 deaths, and a mortality of 0.10 per mille, as compared with the quinquennial average of 0.17. Cholera is not known to be permanently endemic in any part of the Punjab, and the infection appears to be always imported. The widespread epidemic which followed the Hardwar Fair in 1927 came to an abrupt conclusion in October of that year, and no case was reported until March, 1928, when a small outbreak occurred at Rohtak owing to importation of infection from Calcutta. A fresh wave of infection occurred among the pilgrims attending the Sun Eclipse Fair at Thanesar in November; 38 cases occurred during the fair and 203 cases among pilgrims returning from the fair.

There was a very sharp outbreak in Mandi State. This was almost certainly due to importation of infection from the Hardwar Fair of 1927, but no intimation of the existence of cholera in this area was received until 31st March, 1928, as the State has no public health service. During the first week of April there were 36 cases with 26 deaths, and in the middle of the month at Baijnath 28 cases with 18 deaths among a labour force engaged in the construction of the Kangra Valley Railway. These two outbreaks were speedily suppressed, and at the end of April it appeared that all danger was over. Only once during the previous 61 years had cholera been epidemic in the Kulu Valley. Unfortunately carriers from Mandi State must have carried the infection into Kulu Valley, as in May a sudden and explosive epidemic broke out, and persisted till August. There were 1,746 seizures with 1,164 deaths; figures which show how heavy cholera mortality is amongst a primitive people. Unfortunately news of this outbreak did not reach the Director of Public Health until 5th June. Immediate assistance was rushed to this somewhat inaccessible and remote spot, and the most vigorous measures taken. Fortunately, as a result of these measures, the epidemic was stayed and both the Simla Hill States, and Simla and Ambala were protected. It has now been decided to station a small public health staff permanently in the Kulu Valley to deal with future emergencies, and to prevent the heavy loss of life inseparable from an epidemic which is able to obtain a firm hold on the population before the necessary measures to check it can be taken.

The seasonal periodicity of cholera during the year showed peculiar features, for the maximum prevalence was in June, instead of as usual August, whilst a second fresh wave of infection occurred in the cold weather months of November and December. The preventive measures at the Thanesar fair in November were very successful; in Kulu no one could have anticipated a severe epidemic, and the difficulties in combating cholera in this remote region were very great.

Smallpox accounted for 8,764 deaths, or a mortality rate of 0.43 per mille, as compared with the quinquennial rate of 0.40. The disease was as usual more frequent in the urban than in the rural areas, and at its maximum prevalence as usual during the months of May and June. It is hoped that Simla and Lahore will shortly be provided with fully staffed and equipped smallpox hospitals.

For the second year in succession, the incidence of *plague* was unusually low—9,922 deaths in the British

districts, and 1,640 in adjacent areas. The death rate from this disease was 0.40 per mille in the former, as against a quinquennial average of 4.44 in the previous five years. The disease as usual assumed its epidemic form in March throughout the epidemic area. In August not a single death from plague was reported, whilst it recurred later in only mild epidemic form. Colonel Gill attributes the check which the epidemic spread of the disease received during the year largely to the dust storms of 4th to 7th March, associated with a rapid decline of atmospheric humidity. He gives the chief features of the epidemiology of plague in the Punjab during the year as having been progressive shrinkage of the endemic area, combined with a tendency of the disease to persist in the relatively humid districts in the foothills of the Himalayas; the low diffusibility and intensity of the epidemic; its early and complete decline in June, and the restricted character of its recrudescence in the autumn. It actually proved possible during the year to reduce the anti-plague staff, a most notable fact when the previous history of plague in the Punjab is considered. (It would seem clear that the results of decades of vigorous anti-plague measures may now be becoming apparent.)

The fever death rate, as mentioned previously, was unusually low, 15.41 per mille as against the quinquennial average of 20.17. This was due, in part to a welcome absence of influenza in January and February, and chiefly to the unusual climatic conditions of the year, and the very low incidence of malaria in the autumn. *Dysentery and diarrhoea* accounted for a mortality rate of 0.51, as against a quinquennial average of 0.54. The incidence was unusually heavy in the Rawalpindi district.

As elsewhere in India, and especially in the western half of India, where extremes of climates prevail, *respiratory diseases* are an important cause of mortality: death rate 2.57 per mille as against a quinquennial average of 2.55. The greatest mortality is in the winter months, and the urban death rate greater than the rural one. Influenza is partly responsible, and that chiefly in the sub-montane tract, but Colonel Gill is of opinion that respiratory diseases take such a toll of lives in the Punjab that vigorous measures should be taken against them. A special point which he raises—and, in our opinion, one of great importance—is the slackness of municipal committees with regard to house planning; plans are passed which create conditions of insanitation and absence of ventilation which are bound to lead to the widespread propagation of respiratory diseases. He rightly calls attention to the *laissez faire* policy in India with regard to this important aspect of public health.

Colonel Gill's report also includes the Report on Sanitary Works for 1928 by Rai Bahadur Amar Nath Nanda, B.A., M.E., Superintending Engineer, Public Health Circle, Punjab.

Colonel Gill's report closes with certain forcible remarks on the problems of public health administration in a large Indian province, which are of such interest that we quote them below *in extenso* :—

"The year was, it has been shown, an exceptionally healthy year, and, in spite of some disappointments, it is possible to regard with chastened satisfaction, the advance made along the strait and narrow road to Health.

The first stage in the organization of a provincial public health service has been completed, some progress was made in adjusting the administrative machine to the requirements of scientific governance; the efficiency of the department, as well as the demands made upon it, showed unmistakable signs of steady and healthy expansion and last, but not least, the attitude of the public, from the Legislature downwards, towards public health measures was uniformly encouraging.

On the other hand, it is clear that a beginning—only a small beginning—has been made, that some sanitary problems have not yet been envisaged, let alone tackled, and that the provision made for public health measures, both centrally and locally, falls far short of requirements. Indeed, the provincial expenditure upon public

health (after deducting departmental receipts) fell from Rs. 20.9 lakhs in 1926-27 to Rs. 12.8 lakhs in 1927-28.

It is difficult to create an A-1 department with the aid of a C-3 budget, but apart from the question of funds, the manner in which an ever-increasing measure of local self-government can be squared with efficiency in the sphere of public health, is a source of anxious concern. Local Government—of which public health is the very bone and marrow—has not yet passed the first instar and it will need the best efforts of statesmen to discover a *via media* which will provide necessary direction and guidance without unduly interfering with local administrative control.

It is not so much a question of *policy* as of *pace*, but so long as local bodies are amenable to the malign influence of communalism—that cancer of the body politic—so long will counsel be darkened and action paralysed in the sphere of public health.

But these and other disabilities may be only 'growing pains' and it is well, in concluding this report, to take an optimistic view and to dwell upon the evidence contained in this report that, so far as circumstances permitted, a sustained effort was made to meet the pressing needs of the moment and to lay the foundations of future progress. That it is possible to make this statement is largely due to the loyal co-operation and assistance of Assistant Directors, District Medical Officers of Health and all ranks of the department."

The general comment offered on the report by the covering resolution of the Ministry of Self-Government in the Public Health Department, is as follows :—

"Government have read with interest the report of the Superintending Engineer, Public Health Circle, from which it is clear that a large number of sanitary works of public utility have been constructed or are under construction. Reference has already been made to the special water supply scheme for the Thanesar fair, and in addition many other water supply and drainage schemes have been completed. The completion of such schemes is, however, a beginning only, and it is on the successful maintenance and working of the schemes by the local bodies concerned that the safety and convenience of the public depend. Government have read with grave concern the remarks of the Director of Public Health to the effect that several instances came to notice during the course of the year of the complete ruin of costly plants owing to the negligence of the local body concerned, and one or two particularly glaring cases are already under the consideration of Government. Government desire once again to emphasize the personal responsibility of members of local bodies for loss and waste which are the immediate result of their culpable negligence, and where such culpable negligence is established, the liability to make good the loss will be enforced. It is regrettably obvious that local bodies in a large number of cases fail to make adequate financial arrangements for the maintenance of their water-works. All such schemes should be made self-supporting, and that this is not the case at present is clearly brought out in the report. A piped supply of pure water is one of the greatest blessings that can be brought to the homes of the dwellers in towns, rich and poor alike, and a very moderate water tax coupled with the metering of all private connections is sufficient to provide all necessary running costs with a reasonable margin for repairs and replacement. The Urban Sanitary Board has now drawn up a suitable model set of bye-laws for water supply, and Government will in future not sanction any grant for the construction of water-works until they are satisfied that these bye-laws will be accepted and duly enforced.

The vital importance to the life of the Province of adequate public health arrangements in every sphere of the department's activities cannot be exaggerated, and it is impossible within the confines of a short review to express the considered views of Government on all the important matters dealt with in the report. Attention has been directed to certain of the more pressing matters, and for the rest Government must leave the report to speak for itself.

Government have read with pleasure the list of sanitary works of public utility executed by individuals throughout the Province and desire that their appreciation should be conveyed to the gentlemen concerned.

Government desire to thank Lieutenant-Colonel C. A. Gill for an interesting report and for a year of progress and good work generally. Lieutenant-Colonel Gill has earned a reputation extending beyond the Province as an expert on all matters concerned with epidemics, and his strenuous labours over a number of years are undoubtedly bearing fruit. The district medical officers of health, of whom there is now one in every district except Simla, are proving their value by the prompt measures they are able to take whenever an epidemic appears, and it is an instructive fact that the only place in the whole Punjab where an epidemic was not tackled and suppressed as soon as it appeared was the isolated valley of Kulu which had no public health staff at all, a defect which Government have now arranged to remedy."

Correspondence.

THE ORGANISM OF BOVINE LYMPHANGITIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I beg to enclose a letter which has been addressed to the Editor, the *Indian Veterinary Journal*, Madras.

As many of your readers may not see that journal, I should esteem it a favour if you would kindly publish the letter also in your paper.—Yours, etc.,

L. A. P. ANDERSON, MAJOR, I.M.S.,
Offg. Director.

HAFFKINE INSTITUTE, PAREL, BOMBAY,
15th January, 1930.

"Letter dated Bombay, the 15th January, 1930.

From Major L. A. P. Anderson, I.M.S., *Officiating Director, Haffkine Institute, Parel, Bombay.*

To the Editor, 'The Indian Veterinary Journal,' 26, Wallajah Road, Mount Road, Madras.

SIR,—My attention has been drawn to a paragraph under notes, page 6, Vol. VI, No. 1, July, 1929, of the *Indian Veterinary Journal*, which runs as follows:—'A great discovery indeed is the one made by Mr. V. Krishnamoorthy Iyer, I.V.S., that the organism of bovine lymphangitis is identical with the *B. pestis*. We learn that it has been accepted as such after proper test at a conference of the medical men at the Haffkine Institute, Bombay.'

The statement that 'it has been accepted as such after proper test at a conference of medical men at the Haffkine Institute, Bombay' is incorrect. No bacteriological study of the organism of bovine lymphangitis has as yet been carried out in this Institute, and as such its identity with *B. pestis* has not been established by any of the officers of this Institute. I therefore request you to publish this disclaimer in your next issue."

VOLVULUS OF THE SMALL INTESTINE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I was much gratified by your letter promising early publication of my article on volvulus of the small intestine (*Indian Medical Gazette*, January, 1930, p. 9).

In my article I limited myself to certain aspects of the problem of spontaneous recovery. There are others which I could not write about without becoming too speculative; e.g.:—

Are some of these cases due to enterospasm?

What is the nature of the common intestinal colic of India?

What is the best treatment for obstruction, when operation is refused? Some use purgatives with atropine

in large doses; others pituitrin and eserine; others again rely on repeated enemata.

I wish you could find others to write on the subject. It seems to me to be of considerable practical importance. These cases are so frequent that many Indian practitioners advise against operation altogether (though I am sure that they are wrong). I myself am by no means sure whether repeated enemata before operation are desirable or not; it is surprising how often they succeed, but they involve dangerous delay and exhaustion when they fail.—Yours, etc.,

R. C. M. McWATTERS, M.B., F.R.C.S.,
LIEUT.-COLONEL, I.M.S.

C/o GRINDLAY & Co., LONDON,
15th December, 1929.

THE TREATMENT OF MALARIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—It is with the greatest diffidence that I write on the subject of the treatment of malaria, as it has been proved beyond doubt that in quinine we possess a specific remedy for successfully combating this disease. Unfortunately, however, the half starved masses cannot be made to take the "safe dosage of 30 grs. daily for two to three weeks, 20 grs. daily for a month, and 10 grs. daily for two months," on account of the bitter taste, giddiness, deafness, and other complications that occur.

No one questions the importance or success of anti-malarial measures, but until these are started in real earnest all over the country, our duty as medical practitioners ought to be to relieve our patients as quickly as possible by medicines which they have the least objection to taking.

During 1929 I have treated over 4,500 labourers for malaria, and it is my experience that though they do not doubt the efficacy of quinine, they are very reluctant to take it in sufficient quantity on account of its unpleasant after-effects. So, instead of administering quinine bihydrochloride in full doses, I have reduced the dose to 2 grs. at a time twice daily. To it, however, I add quinidine sulphate, grs. 1½. This is given in pill form, and extract nucis vomica and ferri arsenas are added in suitable doses. Podophyllum resin and phenolphthalein are also added when the patient complains of chronic constipation.

The results obtained so far have been so highly encouraging, especially in fever of tertian type, that I take the liberty of writing this, hoping that others in the same situation will give it a fair trial and report their experience in your journal.

The following three cases (out of many) are of sufficient interest to show the efficacy of quinidine sulphate.

Case 1.—Mrs. R. B. M., European female, 40 years. Arrived from England on 17th September, 1929. Fever on 2nd November, 1929, with malaria parasites in the blood films. Full doses of quinine orally for three days, without effect. Quinine bihydrochloride, gr. 10, injected daily for three days. The fever stopped on 10th November, 1929. Patient continued quinine in 30 gr. doses a day for one week. Fever recurred on 20th November, 1929. Quinine administered orally, and continued to 27th November, 1929. Fever again on 30th November, 1929. Quinidine sulphate commenced from this date and continued up to 10th December, 1929. Has had no fever since the 1st December.

Case 2.—Mr. P. S., European male, aged 35 years. Fever, with malaria parasites in blood films, on 6th October, 1929. Three injections, each of gr. 10 of quinine bihydrochloride, followed by quinine orally for ten days. Fever again on 18th October, 1929. Full doses of quinine by the mouth for one week. Fever again on 2nd November, 1929. Given quinidine pills, and this was continued up to 15th January, 1929. Has had no fever since the 3rd November.

Case 3.—Mrs. S., Mahomedan female, aged 60 years. Fever off and on since August, 1929. Could not be induced to take a quinine mixture. Quinidine pills given

on 10th October, 1929, and continued for a fortnight. Has had no fever since the 12th October.—Yours, etc.,

BHUPENDRA K. CHATTERJEE, B.Sc., M.B.,
Medical Officer.

ADAMJEE JUTE MILLS, BELUR.
18th January, 1930.

(Note.—The "safe-dosage" referred to by our correspondent appears to us to be excessive. Present day tendency, we believe, is to abandon the immense, heroic, and long continued courses of quinine which were given in the past. Dr. Chatterjee is in accordance with old and well established opinion, however, in advocating arsenic and iron during convalescence, and in paying special attention to constipation. The reviewer's present practice is to administer Sinton's alkalies and quinine treatment for a continuous period of 12 to 14 days; 30 grs. of quinine a day if the patient will take it, 20 grs. a day if he will not. This is followed by one month's treatment, with one Tabloid after each meal, of Burroughs, Wellcome & Co.'s Tabloid Ferri Citras Co., the formula of which is:—

Ferri et Ammonii Citras	..	gr. 3
Quinina Sulphate	..	gr. 1
Acidi Arseniosi	..	gr. 1/60th

(sugar-coated).

It is probable that the administration of quinine never completely eradicates all the malaria parasites in a patient's blood stream; but if the parasite population can be brought below the febrile threshold by quinine administration, then a prolonged course of arsenic, iron, and quinine in small doses will so improve the hæmatinic system that the patient's own powers of resistance will eradicate the few remaining parasites. At least such a line of treatment appears to be preferable to the prolonged and drastic courses of quinine treatment of the past, with their accompanying misery to the patient, who suffers more from the quinine than he ever did from the malaria.—EDITOR, I. M. G.)

AN EPIDEMIC IN RATS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Rats have been dying here in large numbers for the past one and a half months. Smears of blood from the heart and spleen were sent to the Director, Haffkine Institute, Bombay, and were declared to be free of plague infection. The Principal, Veterinary College, Bombay, is of opinion that the disease from which the rats have been dying is an atypical form of plague. No human case has been recorded to date.

I remember to have read some time ago in the *Indian Medical Gazette* that rats may die under epidemic conditions from a disease called sarcosporidiosis, which is not communicable to human beings. Do you think that the present mortality among rats may be due to this disease? If the mortality is due neither to plague nor to sarcosporidiosis, can any of your readers suggest through your columns the possible cause of such an epidemic in rats?—Yours, etc.,

S. R. INGLE,
S. M. S. Officer.

CIVIL HOSPITAL, RATNAGIRI,
23rd December, 1929.

(Note.—Sarcocystis infection, as a rule, does not give rise to symptoms, though it is recorded in the literature that mice and rats may die from the infection. The parasites especially affect the striated muscles; usually those of the skeletal muscles, but also the heart, larynx, tongue, and diaphragm. Full descriptions of the parasites, whose exact systematic position is still uncertain, are given by Wenyon in his *Protozoology*, and by Knowles in his *Medical Protozoology*, p. 333. It does not seem likely that sarcosporidiosis will account for the epidemic. *Leptospira* infections in rats are usually believed to be symptomless, though the same is by no means the case in experimentally infected guinea-pigs. Whether *Pasteurella* infections occur in the rat we do not know; but if this was the cause it would certainly not have been overlooked by the Haffkine Institute.

Perhaps some of our veterinary readers—if any—might make suggestions?—EDITOR, I. M. G.)

GANGRENOUS STOMATITIS FOLLOWING DYSENTERY.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I request you to kindly publish this record of a case of gangrenous stomatitis following an attack of bacillary dysentery in your correspondence columns.

The patient, a boy aged about 3 years, was suffering from bacillary dysentery for about a fortnight before the onset of gangrenous stomatitis. General debility was probably the predisposing cause. It is usually considered that this rare disease occurs during convalescence from acute fevers, most commonly after measles and infrequently after scarlet fever and typhoid fever. As the occurrence of this condition as a sequel to bacillary dysentery is rare, it may be of interest to the profession in this country.—Yours, etc.,

T. S. NAIDU, L.M. & S. (Hyd.),
Private Practitioner.

RAICHUR, HYDERABAD STATE,
20th December, 1929.

(Note.—Gangrenous stomatitis is not a very rare condition; it is a sequel of several of the debilitating diseases of children. This fact is not always remembered by practitioners in Bengal at least, who administer the treatment for kala-azar in a very large percentage of such cases, whether the previous history is suggestive of that disease or not.—EDITOR, I. M. G.)

MYCETOMA IN RAMNAD.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In your editorial in the August, 1928, number of the *Indian Medical Gazette*, I find Ramnad District mentioned as a district where mycetoma is common. I beg to state that none of the hospitals in this district have recorded a single case of endemic origin of mycetoma infection for many years. During the last three years only the Virudunagar and Ramnad hospitals have had cases, and the hospital statistics show that between 1925 and 1927, 7 cases were treated in Ramnad, and 4 in Virudunagar. These all came from outside the district.—Yours, etc.,

T. S. ADISUBRAMIAN, M.B., B.S., B.S.SC.,
District Health Officer.

5th November, 1928.

(Note.—We regret that this letter was not published earlier. It had been "referred for opinion" elsewhere and overlooked.—EDITOR, I. M. G.)

Service Notes.

APPOINTMENTS AND TRANSFERS.

In modification of Education, Health and Lands Department Notification No. 510-H., dated the 14th March, 1929, Lieutenant-Colonel (now Colonel) C. A. Spravson, C.I.E., M.D., F.R.C.P., V.H.S., I.M.S., Principal and Professor of Medicine, King George's Medical College, Lucknow, is appointed to officiate as Inspector-General of Civil Hospitals, United Provinces, with effect from the 11th March, 1929, and is appointed permanently to that post with effect from the 16th March, 1929.

Lieutenant-Colonel A. D. Stewart, M.B., F.R.C.S.E., I.M.S., Professor of Hygiene, School of Tropical Medicine and Hygiene, Calcutta, and officiating Principal, Medical College, Calcutta, and Superintendent of the College Hospitals, is placed on foreign service under the Indian Research Fund Association for employment as Director designate of the Public Health Institute, Calcutta, with effect from the 1st October, 1929.

On return from leave, Lieutenant-Colonel W. L. Harnett, M.B., F.R.C.S., I.M.S., was re-posted as Superintendent, Campbell Medical School and Hospital, Calcutta,

with effect from the afternoon of the 15th December, 1929.

Lieutenant-Colonel F. E. Wilson, I.M.S., an Agency Surgeon, on return from leave is posted as Residency Surgeon, Kashmir, with effect from the 19th December, 1929.

Lieutenant-Colonel V. N. Whitmore, O.B.E., F.R.C.S. (Eng.), I.M.S., is appointed to be Civil Surgeon, Simla (West) with effect from the 1st March, 1930.

Major J. P. Huban, O.B.E., I.M.S., an officiating Agency Surgeon, is confirmed as an Agency Surgeon under the Government of India in the Foreign and Political Department.

The services of Major M. Fazluddin, O.B.E., I.M.S., are placed temporarily at the disposal of the Government of the Punjab for employment in the Punjab Jail Department with effect from the 1st January, 1930.

On relief by Major S. S. Sokhey, I.M.S., Major W. J. Webster, M.C., I.M.S., Officiating Assistant Director, Haffkine Institute, Bombay, is attached to the Institute as Supernumerary Officer with effect from the 6th December, 1929.

On reversion from the cadre of Agency Surgeons under the Government of India in the Foreign and Political Department, the services of Major M. Fazluddin, O.B.E., I.M.S., are placed at the disposal of the Government of India in the Home Department with effect from the 1st January, 1930.

On return from leave Major A. C. Craighead, I.M.S., an officer of the Medical Research Department, is posted as a Supernumerary Officer at the Central Research Institute, Kasauli, with effect from the date on which he assumes charge of his duties.

LEAVE.

Major G. Covell, M.D., I.M.S., an officer of the Medical Research Department, who was granted combined leave for thirteen months under Education, Health and Lands Department Notification No. 2200-H., dated the 20th December, 1928, is permitted to return to duty on the 6th September, 1929, and the unexpired portion of his leave on half average pay is cancelled.

Lieutenant-Colonel B. Higham, I.M.S., Chemical Analyser to the Government of Bombay, is granted leave on average pay for seven months with effect from 15th April, 1930, or date of availing.

Lieutenant-Colonel D. G. Rai, I.M.S., District Medical Officer, South Kanara, is granted leave on average pay for fifteen days from the 3rd January, 1930, with permission to prefix the holidays from the 21st December, 1929, to the 2nd January, 1930, to his leave.

Major J. A. Sinton, V.C., O.B.E., I.M.S., Director, Malaria Survey of India, Kasauli, on foreign service under the Indian Research Fund Association, is granted leave on average pay for 2 months in India with effect from the 1st January 1930 or subsequent date on which he may avail himself of the leave. His services are placed at the disposal of the Director-General, Indian Medical Service, with effect from the date on which he proceeds on leave.

Major G. C. Maitra, I.M.S., Officiating Assistant Director, Central Research Institute, Kasauli, is granted leave on average pay for 8 months combined with study leave for 6 months with effect from the 1st September, 1929.

PROMOTIONS.

Major to be Lieutenant-Colonel.

A. N. Palit, F.R.C.S.E., I.M.S., dated 29th July, 1929. The promotion of the undermentioned officers to the rank of Major is ante-dated to the dates mentioned:—

T. S. Shastri, M.B., dated 1st February, 1926.

Ranjit Sen, dated 7th August, 1928.

Captain to be Major.

J. W. F. Albuquerque, M.B., dated 22nd December, 1929.

RESIGNATION.

Lieutenant W. McCoach, M.B., I.M.S., relinquished his probationary appointment from the 24th October, 1929.

RETIREMENTS.

Colonel W. S. Willmore, M.D., I.M.S., with effect from the 7th August, 1929.

Lieutenant-Colonel J. W. Watson, C.I.E., C.B.E., I.M.S., from the 8th November, 1929.

Lieutenant-Colonel J. Forrest, I.M.S., with effect from the 4th November, 1929.

Major M. Prasad, I.M.S., dated 28th October, 1929.

NOTIFICATION.

Officers who are now serving on temporary commissions in the Indian Medical Service and have been gazetted to temporary rank have been granted substantive rank on their temporary commissions equivalent to and in substitution for the temporary rank so gazetted, except in the case of temporary rank granted to officers in consequence of their being called upon to perform the duties of a rank higher than their substantive rank.

NOTE.

PITUITARY EXTRACT. "B. D. H."

An interesting little brochure, which we have received from the British Drug Houses, Ltd., gives an account of the methods of testing and uses of this preparation. The method of standardisation employed is that recommended by the Medical Research Council, and consists of testing the effects on the uterus of a virgin guinea-pig, as compared with the effects of a similar preparation obtained in accordance with the procedure recommended by the International Committee on the Standardisation of Biological Products. The graph reproduced shows that the "B. D. H." preparation is of equal, or slightly superior, value to the standard preparation; a response is obtained in dilutions of the order of 1 : 10,000,000. A second test is to test the pressor action on the blood-pressure of a decapitated cat. Both tests show that the preparation is fully active.

The uses of this preparation are numerous. In inducing labour repeated small doses may be given together with castor oil orally. It is of value in surgical shock, in intestinal stasis, as a safeguard against hæmorrhage in operations on the nose and throat, in the polyuria of diabetes, in insulin hypoglycæmia, and in heart failure where an immediate effect is required. It is put up in ampoules for intramuscular injection in two strengths, 10 and 4 international units respectively.

The brochure contains a useful list of references from the literature, and will be of interest to our readers.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and all other business should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers, relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India, Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

FORECAST OF THE PROBABLE MAJOR VARIATIONS IN CHOLERA, SMALL-POX AND PLAGUE IN INDIA DURING 1930, BASED ON THE METEOROLOGY OF 1929.

By Sir LEONARD ROGERS, Kt., C.I.E., M.D.,
F.R.C.P., F.R.S.,

MAJOR-GENERAL, I.M.S. (*ret'd.*).

(Received for publication 23rd February, 1930.)

As the result of three very laborious years' study of some sixty years' sanitary and meteorological records for all parts of India, I showed that the major epidemics of small-pox, cholera and plague are dependent on antecedent meteorological variations which makes it possible to forecast them several months before their development with a fair degree of accuracy. Such a correct forecast based on my methods was actually made by the sanitary officer in the Southern Deccan in the case of the cholera epidemic of 1927, and that in Sind in 1929 so clearly followed very deficient rainfall during the previous monsoon and winter months, that I presume it was also foreseen by the sanitary authorities in accordance with the previous similar sequence of events in 1885 and 1892, pointed out in my memoir on cholera incidence (*Indian Jour. Med. Research*, 1928).

Working in London I am handicapped by receiving the vital statistics and meteorological data some two months later than they are available in India, but in order to put my theories to a very rigid test I propose to publish forecasts of the probable major variations of the three great epidemic diseases of India, in the hope that should they prove in any degree correct during the next three years or so, the method may subsequently be taken up under the more advantageous conditions obtained in India itself. That such forecasts may be of great practical value is proved by the fact that in the case of the South Deccan cholera epidemic of 1927 the divisional sanitary officer warned the authorities some time before the appearance of any cholera in his districts that on the rules laid down by me in 1926 the failure of the previous monsoon rains, combined with the high degree of susceptibility due to the practical absence of cholera from that area during the previous two years, rendered an epidemic of cholera very probable. Moreover, as soon as the first few cases appeared he advised the prohibition of a local pilgrimage, but the authorities decided that it was too late to do so, and severe cholera broke out at this fair, and although subsequent fairs were prohibited, a widespread epidemic followed, which was apparently the origin of an outbreak in the Persian Gulf soon

after, which, but for our presence in Iraq, would probably have spread to Europe with appalling results in Russia, as happened in 1851-53. My full memoir had not then been published or it would have been possible to foresee the South Deccan outbreak with practical certainty at least a month before its occurrence by the exceptionally favourable 1927 high spring absolute humidity in the South Deccan as shown on page 105 of my memoir, and it is of great interest to record that I was fortunate enough to meet the head of the first infected district, who agreed with me that had he received longer warning based on the high absolute humidity data, he could have prohibited the incriminated fair in time to check the outbreak. This example should suffice to convince the sanitary authorities in India that my methods are at least worthy of their attention.

Meteorological data of 1929 unfavourable for forecasts.—Fortunately for India the monsoon rains of 1929 were remarkably well distributed, for the only material defect in the British Provinces, with which alone I deal, was the moderate deficiency of 16 per cent. in the United Provinces, and the only significant excess was due to heavy rains on the North-West Frontier and in Sind in July, which is less important from my present point of view than in the later monsoon months. My forecast this year will therefore be mainly of a negative character, but not necessarily less valuable, should a forecast of the absence of epidemics over most of India prove correct.

CHOLERA INCIDENCE.

Factors influencing.—These were fully described in my memoir and are briefly: (1) Low monsoon and winter rains of the previous year, (2) a high degree of susceptibility due to absence of recent epidemic prevalence, and (3) a favourable absolute humidity of about 0.400 and over at the time of the usual seasonal increase of cholera in the particular area. The first two sets of data are available some months before an outbreak, the third is only known shortly before, so only the first two can be used in this forecast, although the third is also important to watch in some areas. In my memoir I showed that no less than 40 out of 41 epidemics in India during 45 years had been preceded by deficient rains, and the one exception was due to high spring absolute humidity in a twelve-yearly Allahabad Kumbh Fair year, which Fair has recurred once more in 1930. I also showed that cholera does not spread in periodic waves from Bengal as held for a century, for the yearly incidence curves over 45 years are different in Assam, Eastern Bengal, Western Bengal and in Bihar, as well as in the East and the West of the United Provinces, which forms one huge north-eastern endemic area, while South-East Madras and the West Coast of Bombay are distinct endemic areas from which cholera also spreads as in 1875. Smaller areas than provinces

have therefore to be dealt with in making a forecast, and the most important of these are shown in Table I, in which a — sign indicates previous low cholera incidence and low monsoon rainfall respectively, which are favourable to increased cholera, and + signs have the opposite significance. Two signs, such as — —, indicate high degrees and single signs, such as —, only moderate departure from the normal, and it is only the major degrees that indicate severe epidemics, and it will be noted that they are practically absent as regards rainfall from Table I

the Surma Valley of Assam, and low prevalence in Sind after last year's epidemic, due to failure of the 1928 monsoon and the ensuing winter rains. With the important exception of Bihar and the United Provinces, no great departure from the average of the last ten years is to be expected in the other areas dealt with, although I have ventured to indicate the direction which such slight variations may be expected to take, although I recognize that in view of the slight departures from the normal monsoon rains there is only a reasonable probability of their being

TABLE I.

Forecast of probable cholera incidence in India in 1930.

Area.	PREVIOUS PREVALENCE. MONSOON 1929.					Forecast.
	1927.	1928.	1929.	6—9.	10.	
E. Bengal	+	?	—	+	—	About average incidence.
W. Bengal	+	?	—	—	+	do.
Assam Valley	+—	—	—	++	+	Average to somewhat low.
Surma Valley	+	—	—	—	—	Moderate increase over average.
Orissa	+—	+	+—	++	—	Average to somewhat low.
Bihar	—	++	+—	—	++	Climatic conditions normal. Allahabad Kumbh Fair will cause considerable excess.
E. United Provinces ..	+—	+	+—	+—	+—	Low September rains favour cholera. Allahabad Kumbh Fair will cause excess. This may be great if winter rains fail or if February and March absolute humidity is in excess as in 1894.
W. United Provinces ..	+—	+—	—	—	+—	Deficient monsoon rains favour cholera, so excess following that in E. United Provinces to be feared.

S. E. Madras	+—	+—	+—	—	—	Average to some excess.

owing to the favourable 1929 monsoon. A + — sign indicates no material variation from the normal. As in Assam and Bengal the cholera season commences during the last three months of the year, the forecast relates to the period from October 1929 to September 1930 and in South-East Madras from December to November. Table I will allow the data regarding previous cholera prevalence and the 1929 monsoon rainfall in each area and their probable influence on 1930 cholera incidence to be seen at a glance, and in view of the practically normal rainfall in most of them affording little likelihood of great departures from the average it is unnecessary to discuss them all in detail. An increase over the average of the last ten years may be expected in

fulfilled. The deficiency of the latter part of the monsoon rains in the West of the United Provinces is of greater importance than usual owing to the Allahabad Kumbh Pilgrimage in January and February 1930, for although I pointed out in my memoir this occurrence does not usually seriously infect the western United Provinces divisions owing to its occurring when the absolute humidity is too low for epidemic cholera in the west, yet should the epidemic prevalence of cholera in the east of the United Provinces, which has followed each of the four previous Allahabad Kumbh Fairs from 1882 to 1918, recur in 1930, the western divisions are more likely to be infected on account of their 1929 low rainfall. Should the winter rains be deficient in the United

Provinces the danger will be enhanced in both parts of the province.

The 1930 Allahabad Kumbh Fair and Cholera in Bihar and the Eastern United Provinces.—In Chart XIII of my memoir I demonstrated that the cholera incidence curves during 35 years in Bihar and the Eastern United Provinces ran closely parallel owing to main rises occurring in the Allahabad Kumbh Fair years, and in those with very deficient monsoon rains affecting both areas. Moreover, I showed that the extent of the Kumbh epidemics from 1882 to 1918 was dependent on the rainfalls and the January to March absolute humidity, and not on the excellent sanitary measures at the fairs since 1894, which only deal with two or three square miles out of some 100,000 square miles of the endemic cholera area of the two provinces, through whose insanitary villages and towns some 3,000,000 pilgrims pass to and from the Fair. The fact that the 1882 Fair, with no proper sanitary precautions at the Fair site, caused less cholera than the next three fairs, with good sanitation at the camp, suffices to prove this obvious inference. I also showed that the high cholera incidence in 1894 as compared with that of 1882 was due to the exceptionally high and favourable absolute humidity at the time in 1894 compared with exceptionally low readings in 1882 (*see p. 129 of my memoir*). The extent of the 1930 epidemic will largely depend on whether the absolute humidity in Western Bihar and Eastern United Provinces is well below the critical level of 0.400 in January to early March this year as in 1882, or whether it approaches that level, as in the bad cholera year 1894, as well as on whether the winter rains are good and so less favourable to high cholera incidence. These data are not yet available in London at the time of writing in the last week of January, but they will be available to the sanitary authorities by the time this forecast appears, so this crucial point is referred to in Table I and will largely determine the extent of the cholera epidemic, which is apparently inevitable in Bihar and the Eastern United Provinces this year, and which may affect to a less extent the West. Owing to the favourable monsoon rains in the Eastern United Provinces and Bihar, unless the absolute humidity in January to March is in excess of the normal, the cholera epidemic due to the Kumbh Fair of 1930 is likely to be less severe than in 1894, 1906 and 1918.

SMALL-POX.

Factors influencing yearly incidence.—A comprehensive study of the monthly provincial small-pox variations in India in relation to meteorology during 48 years was published by me in No. 106 of the *Special Report Series of the Medical Research Council*. I there showed that the yearly decline in the disease during the rains in the seven provinces most affected by the south-west monsoon was related to the high

absolute humidity at that season, and that the small-pox epidemics which occur mainly in the north-west and central part of India are related to comparatively low monsoon absolute humidity due to partial failure of the monsoon rains in the previous year, but in the less affected damp areas of Bengal, Assam and Madras low autumn absolute humidity favours subsequent increased small-pox prevalence. Another important factor is the prevalence of the disease during the previous few years, as in a year immediately following an epidemic, favouring low absolute humidity will have comparatively little effect in causing another rise; on the other hand after a series of four or more years of low small-pox a considerable rise may occur, due to the accumulation of susceptible persons, in the absence of specially favourable low absolute humidities. Only considerable variations from the average absolute humidities are of value in forecasting epidemic increases.

Meteorological conditions during 1929.—The remarkably well distributed monsoon rains of 1929 naturally resulted in only slight variations in the monsoon absolute humidity in most of the provinces of India, consequently few material variations from the average small-pox prevalence in 1930 are to be expected. The monthly distribution of the rains, as well as their totals, affect the average absolute monsoon absolute humidities; it is for this reason that the humidity data are the more important in making forecasts. The provincial variations of the 1929 absolute humidities which mostly affect the next year's small-pox are given in Table II, together with the small-pox incidence of recent years, and their probable bearing in the incidence of the disease in 1930 is indicated.

Discussion.—Only variations of about 0.030 to 0.050 and over from the average absolute humidities are closely related to small-pox variations in any particular province, so in absence of very high degrees in any of the data, which are based on the figures of a representative place in each province, no severe epidemic of small-pox is likely to occur in India during 1930. Bihar and Orissa, the North-West Frontier Province and the Central Provinces show moderately low absolute humidities, which are liable to be followed by some increase of small-pox over the average of the ten years 1919–28 given in Table II, but in the case of the North-West Frontier the fact that small-pox has been fairly prevalent in three out of the four previous years makes it unlikely that the increase, if any, will be material. The same remark applies to Bihar and Orissa, and the year as a whole presents unusually indefinite data on which to base a reliable forecast.

In Madras and Burma the small-pox incidence is most closely related to the absolute humidity from November to January which is not yet available.

TABLE II.
Forecast of probable small-pox incidence in India in 1930.

Province.	10 years' average.	Previous Prevalence.			ABSOLUTE HUMIDITY.			Forecast.
		1927	1928	1929	Months.	Average.	Variation from normal.	
Assam	0.42	0.76	1.23	0.09*	10—11	0.675	— 0.008	Average to low.
Bengal	0.42	0.9	0.25	0.1*	10—11	0.726	— 0.007	Average to low.
Bihar and Orissa ..	0.40	1.0	0.4	0.1*	10—11	0.588	— 0.038	Average to some excess.
United Provinces ..	0.12	0.17	0.07	0.13*	10—11	0.519	— 0.001	Average to some excess.
Punjab	0.37	0.48	0.43	0.18*	6—9	0.833	— 0.023	About the average.
N. W. F. P. ..	0.30	0.08	0.27	0.24*	7—9	0.708	— 0.045	Above the average.
Central Provinces ..	0.18	0.20	0.10	0.05*	6—9	0.710	— 0.037	Above the average.
Bombay	0.24	0.27	0.27	0.46*	6—10	0.676	— 0.006	About the average.

* The 1929 rates are based on the available figures from January to November with the estimated prevalence in December. They are not likely to vary from the actual data by more than a point or two in the second decimal place.

PLAGUE.

Factors influencing annual incidence.—I recorded in 1928 the results of an elaborate analysis of the incidence of plague in relation to climate during thirty years in different areas of India (*Proc. Royal Soc., B.*, Vol. 103, p. 42). This paper, as well as those already mentioned on cholera and small-pox, were sent to all the Directors of Public Health in India. The climatic factors which showed the closest relation to plague incidence proved to be the average mean temperatures in the hot and rainy seasons, and the saturation deficiencies at all four seasons of the year, making six yearly data to be studied, four of which are available before the annual increase of the disease about December in North and Central India, but in the Bombay Deccan the rise of plague occurs during the later monsoon months owing to the mean temperature being then too low to inhibit the disease in that area. Only northern India and the Central Provinces can therefore be dealt with in this forecast, and as the disease is absent or negligible in Assam and Bengal this leaves Bihar and Orissa, the United Provinces, the Punjab and the Central Provinces. The four climatic factors of the previous year which mainly influence the disease in any year in these areas are the monsoon temperatures, and saturation deficiencies of the hot weather and monsoon seasons, and that from October to December, but only the first two months' figures of the last are available at the time of writing. Saturation deficiency is obtained by deducting the monthly absolute humidity from the saturation point at the mean monthly temperature; it is a measure of the drying power of the atmosphere, high degrees of which, as well as high

temperatures, are inimical to the life of the rat-flea carriers of plague infection. The average monthly figures I worked out for thirty years of these data enables the degree of excess or deficiency to be calculated for any year, and as high temperatures and high saturation deficiencies, indicated by + signs in Table III, are unfavourable to subsequent high plague incidence, and *vice versa*, a considerable preponderance of + signs indicates the likelihood of low subsequent plague, and a series of — signs indicates the probability of subsequent increase of plague over the average of recent preceding years. Two ++ and two —— signs respectively indicate a well marked variation from the normal, and a single + or — sign only a moderate variation of much less significance, so that unless some double signs appear in the table no great change in the plague incidence is to be expected. The climatic data as far as they are available for 1929 are given in this manner in Table III and the deductions from them are indicated. It must also be remembered that, just as with small-pox, after a year or two of high plague incidence any factors favouring high plague incidence will have less effect than after some years of low incidence. Owing to the multiplicity of the factors, plague forecasting is more complicated and difficult than that of cholera and small-pox and my full paper should be studied by any one attempting this task.

Forecast.—It will be seen from Table III that in no province during 1929 were the climatic conditions very favourable or unfavourable to plague prevalence during 1930, such as was shown by a great preponderance of — or + signs in years of high and low incidence in the tables in my former paper. There is only then

TABLE III.

Forecast of plague incidence in 1930 in North and Central India; saturation deficiencies.

Province.	Monsoon Temperature.	In Hot Season.	In Monsoon Season.	October—November.	Forecast.
Bihar and Orissa ..	+—	++	++	+—	Below the average.
United Provinces ..	+—	+	+—	+—	About the average.
Punjab ..	+—	+	—	+—	Average to slight excess.
Central Provinces ..	+—	++	+—	++	Below the average.

Note.—High saturation deficiency in January to March and high mean temperatures in March and April lessen the incidence of plague, and *vice versa*. The above forecast will be influenced by any material departures from the normal in these respects in the climatic conditions in the early months of 1930.

a fair degree of probability of moderate variations of plague during 1930 in the directions indicated in the table, namely rather low incidence in Bihar and Orissa, and especially in the Central Provinces, and possibly slight excess in the Punjab.

As a whole 1930 is likely, if my forecast is fairly correct, to be one of no very great variations of cholera, small-pox and plague in India from the average incidence of the last decade, except the regularly recurring twelve-yearly Allahabad Kumbh Fair cholera one in Bihar and the United Provinces.

THE *ANOPHELES STEPHENSI* PROBLEM IN CALCUTTA.*

By B. C. BASU, M.Sc.,

Entomologist, Spirochaetosis Transmission Enquiry,
Calcutta School of Tropical Medicine.

THE seasonal prevalence of *Anopheles stephensi* Liston has been studied in Calcutta for one year, viz., from July 1928 to June 1929, in an area almost one square mile in extent in Central Calcutta, with a view to studying this complex problem and the best methods of control of this notorious malaria carrier species of anopheline in Calcutta, the second city of the British Empire. The area under survey is bounded on the north by Mechuabazar Street and Cotton Street; on the south by Bowbazar Street, Lalbazar Street and Dalhousie Square North; on the east by Amherst Street; and on the west by Charnock Place and Clive Street. It consists of ward 8, and parts of wards 7 and 9. According to the latest census in 1921 the population and number of occupied houses in this area were as follows:—

	Population.	Number of houses occupied
Ward 7 ..	32,959	4,530
Ward 8 ..	38,510	7,125
Ward 9 ..	69,670	15,115

* Being a paper read at the Medical and Veterinary Research Section of the Indian Science Congress, Allahabad January, 1930.

The prominent places of public importance in this area are the Bengal Secretariat buildings, the premises of the Calcutta School of Tropical Medicine, the Medical College and allied hospitals, Calcutta University, the Presidency and

Fig. 1.—Sketch map of the area of Calcutta surveyed.

Sanskrit Colleges, the Marwari Hospital, the Indian Association for the Advancement of Science, the Royal Exchange, and a large number of banks and mercantile offices. Fig. 1 gives a map of the area in question.

The land may be considered to be more or less flat, though it has a very slight slope towards

the east. It has filtered and unfiltered water supplies and underground drainage. The land is of alluvial soil, but its upper surface, except the *busti* areas and open lands, is covered with cement under the houses, and pitch on the roads. The area is occupied mostly by Bengali Hindus and Marwaris and Mahomedans, together with very few members of other communities, and the houses comprise densely aggregated Indian quarters and residential quarters of *busti* type. There is one big tank in the area—College Square tank.

During the period of observation the temperature rose as high as 106.2°F. in March. March to June are the hot months with maximum temperature varying from 104°F. to 106.2°F. The minimum temperature fell as low as 52.7°F. in February. The minimum relative humidity, taken at 4 p.m., rose as high as 95 per cent. in July and September, and fell as low as 22 per cent. in March. The total rainfall of the period was 54.86 inches. Appendix I gives a more detailed record of the meteorological observations.

No detailed survey of malaria or of the mosquitoes in Calcutta city has hitherto been published. In 1898 Sir Ronald Ross recorded that there was but little human malaria in Calcutta. In 1901 Professor Stephens and Col. Christophers made some observations on the anopheline mosquitoes and malaria of Calcutta. They recorded the spleen rate as zero, and found *A. rossi* and *A. fuliginosus*. Here it should be mentioned that *A. stephensi* was first described by Liston only in 1901. In February 1900 Sir Leonard Rogers studied the relationship of the drinking water, water-logging, and the distribution of Anopheles mosquitoes to the prevalence of malaria north of Calcutta along the bank of the Ganges. In Chitpur-Cossipore he recorded the spleen rate as 11.2 per cent., the smallest figure obtained for any of the municipalities examined, a finding which he explained by the fact that this municipality had a filtered water supply, though water-logging was most abundant in this area.

In the same year Dr. Neild Cook investigated the connection between the presence of Anopheles mosquitoes and malaria in the city of Calcutta. In three months he found 89 tanks with abundant anopheline larvæ. In 1902, Col. S. P. James, in his report on "Malaria in India," first recorded *Anopheles stephensi* Liston in Calcutta. He examined 140 children and found a spleen rate of zero, and dissected 352 anopheline mosquitoes but found none infected. In 1907 the late Dr. Annandale found *A. stephensi* in the gardens of the Indian Museum. Alcock, Lloyd, Burkill, Bentham, Adie, Daniels, Annandale, James and Liston, and Brunetti collected 8 species of Anophelines and some Culicines from Calcutta—the results being recorded by Theobald and Brunetti. In 1906-7 Dr. B. Brahmachari carried out observations on malaria and anophelines in Chitpur-Cossipore. He

found four species of Anophelines in this area, viz., *A. rossi*, *A. fuliginosus*, *A. sinensis*, and *A. barbirostris*. Dr. U. N. Brahmachari made some observations on the anophelines breeding in the Campbell Hospital; he collected some larvæ from an old tub, which were bred out into adults, and identified by Col. Christophers as *A. stephensi*. In 1912 Col. Fry reported on the history of malaria in Calcutta, noting that the place had been very malarious from the commencement of the British occupation, and studying early records of the days of the East India Company. In the same year Mr. Paiva published a paper on observations of the mosquitoes of the fringes of Calcutta. He did not record any *A. stephensi*.

An enquiry into the prevalence of *Aedes ægypti* (*Stegomyia fasciatus*) in different parts of India was ordered in 1912 by the then Director-General, Indian Medical Service, and from August 1912 to January 1913 Major McGilchrist made a *Stegomyia* survey of the port of Calcutta. In 1913 Col. James published a paper on the practicability of *Stegomyia* reduction in Indian sea ports, with a view to the protection of India from yellow fever. In this connection he studied the conditions in Calcutta, and suggested the provision of a constant high pressure water supply as the first step that should be taken to reduce these mosquitoes. In 1915 Col. Christophers, on instructions from the Director-General, I. M. S., visited Calcutta to advise with regard to the best methods of carrying out a survey of the *Stegomyia* problem in Calcutta. He suggested an improved water supply, as an intermittent one leads to water storage and *Stegomyia* breeding. In 1915-1916 Dr. Nandy carried out observations with regard to *Stegomyia* in two typical selected areas in Calcutta.

In 1916 Col. Christophers pointed out the necessity for a complete scientific survey on Calcutta city, extending over five years and dealing with all mosquitoes which carry disease, and this measure was endorsed by a special conference convened to frame a scheme for securing better sanitary control over the port of Calcutta and its environs. This survey, however, has never been carried out. In 1920 Mr. M. O. T. Iyengar published a preliminary report on malaria in Calcutta city; he recorded *A. stephensi* breeding in the city, and found spleen indices of from 2 to 10 per cent. in the suburbs. In 1922 Dr. S. N. De collected 1,460 anopheline mosquitoes from Districts III and IV of Calcutta; he found 1 per cent. of them to be *A. stephensi*. The reports of the Health Officer of the Calcutta Corporation for 1922 to 1927 state that the death rate from malaria varied from 1.1 to 1.6 per mille during these six years, the maximum number of deaths from this disease being generally recorded in December.

* * * * *

In the present instance an *Anopheles stephensi* survey was carried out once a month for twelve months in the area described. Out of 4,119 likely breeding places, larvæ were found in 1,131, the total number of larvæ collected being 27,498. The largest catches of larvæ took place in July, and the lowest in December. A detailed monthly record of larvæ, breeding places, and their percentages is given in Appendix II.

The buildings, *busti* huts, etc., from which *A. stephensi* were collected may be classified under the following twelve headings, being placed in order of importance:—

- (x) Mahomedan mosques.
- (xi) A church.
- (xii) Hindu hotels.

Although occupied buildings heads this list, it should be mentioned that the number of *busti* huts in the area reported on is but a very small fraction of the number of pukka buildings. The detailed monthly record is given in Appendix III.

In all twenty-one types of receptacles were found to be breeding *A. stephensi*; these are shown in Fig. 2.

Fig. 2.—Types of breeding places of *Anopheles stephensi* in Calcutta.

- (i) Occupied buildings.
- (ii) *Busti* huts.
- (iii) Dyeing and cleaning firms.
- (iv) Waste land and gardens.
- (v) Roads.
- (vi) Mahomedan hotels.
- (vii) Stables.
- (viii) Buildings under construction.
- (ix) Restaurants.

The detailed monthly record with reference to these is given in Appendix IV. The receptacles concerned were as follows:—

(1) *Choubachas*.—These are masonry reservoirs for the storage of filtered water; they vary in size, but generally have a capacity of from 50 to 500 gallons, or more. During the year 982 of these were examined, and 286 were found to harbour *A. stephensi* larvæ. They were mostly

found in pukka buildings, and only a few in *bustis*, since a piped water supply to *busti* houses is but a recent development in Calcutta.

(2) *Cisterns*.—These are made of galvanized iron sheets of standard thickness, and are mostly used as reservoirs for storage of unfiltered water to flush latrines, etc. Every house has at least one on its roof; their capacity is proportional to the number of latrines in the house, the Corporation rules demanding a capacity of 60 gallons per latrine. In the area under consideration most of the buildings are old type Indian quarters; the kitchens are on the ground floor in the same block as the dwelling rooms; and middle class Indians, as a rule, instead of using gas or electric stoves, burn coke and wood for cooking purposes. As a result of the repeated warnings of the Smoke Nuisance Committee, pointing out the increasing number of cases of diseases of the lungs in Calcutta, and the damage done to permanent buildings by coke and wood smoke, the inhabitants of these buildings are gradually shifting their kitchens to the roofs of their houses. This results in an increased demand for filtered water on the roof, but, as the pressure of the filtered water supply is only a few feet in the city, people collect filtered water in a *chaubacha* in the ground floor and thence pump it into a cistern on the roof. On enquiry, the dealers in plumbing material and goods informed me that the sale of pumps and cisterns is rapidly increasing in the city. Thus, the introduction of roof kitchens may lead to smoke abatement, but, unless there is a sufficiently high pressure and a continuous one of filtered water, this will add to the danger of *A. stephensi* breeding in Calcutta. *A. stephensi* larvæ were collected from 162 out of 560 cisterns examined during the year.

(3) *Wooden barrels*, (4) *Earthen haudis*, (5) *Earthen tubs*, (6) *Earthen jars*, (7) *Kerosene tins*, (10) *Iron tubs*, (15) *Iron barrels*.—These receptacles are used to a greater or less extent by the poorer classes of people for storing filtered water; some of them are discarded and rain water collects in them, and they thus form suitable breeding places for *A. stephensi*. Appendix IV shows the correlation between these types of receptacle and *A. stephensi* breeding. Some of the earthen tubs are used as garden tubs in which rain water is collected, whilst some of the iron tubs are used as fire buckets in buildings from which *A. stephensi* larvæ were collected.

Such receptacles such as (8) *tin mugs*, (9) *iron frying pans*, (11) *a wooden box*, (13) *a glass phial*, (14) *a motor mud guard*, (16) *a tin box*, (17) *a teapot*, (19) *cups*, and (20) *a deserted fireplace*, from which *A. stephensi* larvæ were collected, were usually found discarded and uncared for.

(12) *Pitch barrels* were mostly found by the roadside. After the pitch has been used up in repairing the roads, the empty barrels are not

promptly removed; this leads to the accumulation of rain water in them, and they thus become suitable breeding sites for *A. stephensi*.

(18) *Garden fountains* are not very common in the area. One of them was found breeding *A. stephensi*, however.

(21) *Pukka drains* have been found in some instances to breed *A. stephensi*, when they were found blocked by dirt and with the water stagnant. *A. stephensi* larvæ were not found in the tank in College Square. Appendix V shows the correlation between *A. stephensi* breeding receptacles and types of houses, etc.

* * * * *

From the nature of the breeding places discovered and described, it is abundantly clear that the reservoirs of filtered and unfiltered water in the centre of Calcutta city are the main source of the *A. stephensi* breeding in the city. These constitute such danger with regard to malaria transmission as may exist; they present a very much more serious danger with regard to the transmission of dengue by *Aedes ægypti* (and even possibly of yellow fever, if introduced). James (1913) and Christophers (1915) have already stated that the intermittent and low pressure of the Calcutta water supply is the main cause of mosquito breeding in the city, and have suggested the obvious remedy. The Act of 1876 required the Calcutta Corporation to supply filtered water continuously from 6 a.m. till 9 p.m. at 10 feet pressure, and actually at 50 feet pressure between 7 and 9 a.m. and 5 and 6 p.m. The provision with regard to the obligation of the Corporation to supply a continuous water supply was included in a Bill, which subsequently became the Act of 1899. This measure was based on the experience of various engineering experts, who held that a continuous water supply resulted in a reduction of waste. Moore's scheme, which is now partly in operation, when completed, should yield 80 gallons per head per day, and should enable the Corporation to carry out the terms of the Act.

Calcutta city must have provided suitable breeding places for *A. stephensi* almost from time immemorial, when tanks and wells were plentiful. In 1820 the "Fever Hospital Committee" reported that Hindus use the Ganges water which they collect in vessels, and Europeans rain water which they collect in "Pegu" jars, whilst—in the absence of any knowledge of the life history of mosquitoes—it is most unlikely that such receptacles were kept covered.

* * * * *

Chart (Fig. 3) shows the correlation between meteorological conditions and *A. stephensi* breeding in the area in question in Calcutta city. It will be seen that there is an exact correlation between the curve for rainfall and that for *A. stephensi* breeding. Between November and February the fall of the maximum temperature, minimum temperature, and minimum relative

humidity curves correspond extremely closely with the fall of the *A. stephensi* curve. | graphically in Chart (Fig. 4), and in detail in Appendix VI.

Fig. 3.—Chart showing minimum and maximum temperature, relative humidity, rainfall and *Anopheles stephensi*.

“Relative humidity”—which, for the purposes of this paper, is based on the wet and dry bulb readings at 4 p.m.—has been taken at a time daily when the relative humidity is very low. But for comparative purposes it can be used safely, as in every season of the year the relative humidity is low at that time of the day. The variation in the relative humidity from hour to hour during the day, and also the variations at different seasons of the year, are shown

Fig. 4.—Chart showing the variation of relative humidity at different hours in a day in different seasons.

These values are derived from the records of the Alipore Observatory, and include wet and dry bulb temperatures extending over a period of twenty years; they can therefore be

SOME NOTES ON THE UNION OF EPIPHYSES IN INDIAN GIRLS.

By G. GALSTAUN, M.A., D.M.R.E. (Cantab.), M.R.C.S., L.R.C.P.

Hon. Radiologist, Medical College Hospital, Calcutta.

IN the course of routine radiological work at the Medical College Hospitals, Calcutta, during the past five years, I had often been struck by the differences in ossification times in India as compared with European subjects. As the

matter was of considerable importance from the medico-legal standpoint in determining whether or no a girl was a minor, I was approached by Major Mallaya, I.M.S., Police Surgeon, Calcutta, to make an investigation of the appearances seen in a large number of girls between the ages of eleven and nineteen. My difficulty hitherto, in such examinations, had been to get a really reliable statement of age from the parents. This was solved by the kind co-operation of certain schools and orphanages where the ages of the children were known and accurate records thereof had been kept.

The present work is a preliminary step in a more complete investigation embracing both the times of appearance of ossific centres and their union, in both sexes. This latter investigation must necessarily take some time, but is being done as far as possible.

METHOD OF EXAMINATION.

All the girls had their ages certified by their schools or orphanages—so these may be taken as fairly correct. Owing to limitation of films to be used for the investigation, the radiography was limited to the hand, included the wrist and lower ends of the radius and ulna, and the elbow joints. In the latter case films were made of both aspects, anterior and lateral.

It was difficult in many cases to say bluntly whether a centre had joined or no. This has been got over by the following method. Union has been assumed to be complete when the epiphyseal space has been completely filled in, and the bone in epiphyses and diaphyses is of equal density. The linear epiphyseal scar which persists for some time after union has been disregarded where there are other signs of complete union. Other stages in union have been signified by abbreviations, viz.—

- O No union.
- C+ Commencing union. In these cases the epiphyseal space is present, but is beginning to cloud over. In many cases, fine striæ of bone are seen connecting epiphysis and diaphysis.
- JC+ An earlier stage in the same process.
- N+ Where this process is nearly complete but the epiphyseal line (apart from the scar) can still be distinguished.
- J+ Union just complete.

THE HAND AND WRIST.

A. *Metacarpals and Phalanges*.—It was found that in the majority of cases fusion had taken place between the ages of fourteen and fifteen, and never later than sixteen. R. S. Pater-son(1) in a recent paper in *The Journal of Anatomy* states that the age in European girls examined at the Manchester Royal Infirmary was found to be seventeen. Most of the other authorities, including Cunningham(2), Gray(3), and Frazer(4), give a later date, varying between nineteen and twenty-one.

B. Carpal Bones.—These were found to be well developed in all the cases examined.

C. Lower ends of the Radius and Ulna.—The lower end of the radius was found in a great majority of cases to unite earlier than the corresponding end of the ulna, the difference varying from three months to more than a year in some cases. The figures found were fourteen to fifteen in the cases of the radius, and round about sixteen in the case of the ulna.

The following are the figures given by various authorities.

		Age of Union.	
Author.		L. E. Radius	L. E. Ulna.
Gray(3)	..	18—19	20
Morris(5)	..	20	20
Scudder(6)	..	19—20	—
Poland(7)	..	19—23	18—20
Cohn(8)	..	20—21	20—21
Cunningham(2)	..	21	21
Frazer(4)	..	22	20
Paterson(1)	..	19	19

It will be seen that the figures found in Indian girls are on the whole four years and even more earlier than those found by the most recent observations of Paterson. It is interesting to note the very definitely earlier union in the case of the lower epiphysis of the radius.

LOWER END OF THE HUMERUS.

The centres for the capitellum and trochlea were found to join with the shaft of the humerus between the ages of eleven and fourteen. The great majority at the latter age showed complete fusion.

The epiphyses for the two condyles of the humerus were found as a rule to join the shaft between the ages of thirteen and fourteen. The appearance of the epiphyseal centre for the external condyle, which is given as fourteen years by most European authorities, was found to be much earlier in Indian subjects. It was found in many cases outside this series at ages between ten and eleven. In addition R. S. Paterson found that in 30 per cent. of cases the external condyle ossified as an extension of the nucleus of the capitellum. This was seen in the present series, but the number of girls examined at the earlier ages was not sufficient to confirm the figures given. I append the figures for the times of fusion of these epiphyses as given by various authorities.

Author.		Age of Union.
Cunningham	..	16—17
Frazer	..	17
Spalteholz(9)	..	17
Morris	..	17
Quain(10)	..	16—17
Buchanan(11)	..	17
Roberts and Kelly	..	20—22
Ashurst(12)	..	15
Paterson	..	14 to 15 in the case of females and 18 to 21 in the case of males.

The figures given by Paterson are significant. He has been the first to systematically divide the figures according to sex, and in his paper already referred to shows that there is a considerable difference in the times of union of the two sexes, which is after all to be expected from general considerations.

THE HEAD OF THE RADIUS AND THE OLECRANON.

The figures here were the same as in the case of the centres at the lower end of the humerus, i.e., union was found to take place between the ages of thirteen and fourteen. Paterson gives the figures as between fourteen and fifteen, or a year later.

CONCLUSIONS AND SUMMARY.

The union of ossific centres as found above, takes place considerably earlier in Indian as compared with European girls—the difference in time varying from one to four years according to the centre concerned. Until more work has been done on the subject, all statements on the age of minor girls, based on radiological findings, must be treated with reserve, particularly so when these findings are interpreted in the light of the figures published in European and American text books.

THE PLACE OF NON-SPECIFIC PROTEIN THERAPY IN GYNÆCOLOGY.*

By V. B. GREEN-ARMYTAGE, M.R.C.S. (Eng.),
L.R.C.P. (Lond.), M.B., Ch.B. (Bristol), M.D. (Bristol),
F.R.C.P. (Lond.),

LIEUTENANT-COLONEL, I.M.S.,

Professor of Obstetrics and Gynæcology and Surgeon
of the Eden Hospital, Medical College, Calcutta.

and

DHIRENDRA NATH MITRA, I.M.S. (Cal.),
House Surgeon, Eden Hospital Medical College, Calcutta.

The efficacy of protein therapy has been well recognized for many years, and many of you

* Being a paper read at the Medical and Veterinary Research Section of the Indian Science Congress, Allahabad, January 1930.

will recall that in its early days this method was used for various forms of arthritis, where stimulatory reaction was needed for the relief of pain or increase of movement.

It will be our object to demonstrate that protein therapy has an important place in the treatment of certain gynaecological conditions, and to present to you certain facts which demonstrate that its use is of great value to the surgeon from an operative and prognostic point of view.

Professor Hofbauer of Johns Hopkins was the first to show that in addition to the defensive mechanism of Metchnikoff, the genito-urinary tract of the female is endowed with special cells in and around the cervix and parametrium, which have a special guardian function against sepsis. These guardian cells he called monocytes and clasmatoocytes, and he discovered that not only were they constant and peculiar to the parametrium, but that they multiplied from the moment of conception.

They are to be found in the greatest numbers at the base of the broad ligaments and in the meshes of the cardinal ligaments, having the function and capacity of devouring and destroying pathogenic organisms which may pass

mother as a result of pregnancy. The exact protein we do not know, but if from a prophylactic point of view we wish to raise the resistance of a pregnant patient, there can be no doubt that this can be done by the injection of a non-specific protein such as milk, and this procedure has been adopted in many cases with success before delivery, where from the nature of the labour, and its treatment, sepsis would have followed, the function of the injection having been to raise the number of clasmatoocytes and monocytes.

It is on this analogy, the result of actual practice, that many authorities consider a 5 or 10 c.c. injection of milk is as useful as a similar injection of prophylactic anti-streptococcal serum.

Now, if Nature has provided such guardian cells in the pelvis of a woman which multiply to the stimulus of a protein, it is right and reasonable for us to copy Nature when we may in those gynaecological conditions where the resistance and reaction to inflammation is defective or diminished.

It is on this principle in the main that the gynaecologist uses non-specific protein therapy; for the injection of a foreign protein not only increases the number of phagocytes in the blood

Name... Mrs J.

CASE I.

through the cervix, and not only can they do this but also they cause a vast increase of fibroblasts which limit the progress of inflammation, giving rise to scar tissue.

These facts have been corroborated by many authorities, and it is generally conceded that the increase and multiplication of the guardian cells is due to a protein from the placenta, ovum, or

stream and increases the number of active antibodies, but augments the function of the hæmopoietic organs.

Protein therapy is useful in the following conditions for which operation is either not feasible or not imperative:—

1. The fixed, tender and enlarged displaced uterus.

2. Tender and enlarged tubes and ovaries, accompanied by low fever.

3. Thickened and tender utero-sacral ligaments, with sacrahe.

4. Tenderness and thickening at the base of the bladder.

5. Parametrial exudates.

All these conditions are frequently met with by the general practitioner in India far from expert surgical opinion. At the moment such abominations and anachronisms as douches and plugs are the end-all and be-all of the average practitioner, a procedure which lasts for months and rarely does any good. *Ichabod!*

There is a type of case frequently seen in India in which the injection of a protein is of peculiar importance; we refer to those cases of pus tubes or tubo-ovarian masses which are found in all grades of society. These patients suffer for years and because pus is known, or thought, to be present, operation is considered dangerous. Nothing of the sort: 75 per cent. of those cases are originally gonococcal in whom the pus is sterile, and if doubt exists as to operability, great assistance can be gained from a few protein injections, for it will be found that in the majority of cases, there is no leucocytosis before the injection, and very little afterwards, whereas if the inflammatory mass be of streptococcal origin, there is marked leucocytosis before and after the injections and a very considerable febrile reaction as well.

For instance, let me refer to these two case sheets and temperature charts of Anglo-Indian patients seen and operated upon in September 1929 (Cases 1 and 2). Both of them were cases of pus tubes of long standing, who had had the usual douche and plug business for years. Both suffered from exacerbations of fever and both when seen had normal temperatures and almost normal white blood counts, both were given 10 c.c. of milk intragluteally and as you will see neither had any reaction or rise in the white count. Both were operated on on the same day, and in both cases stinking pus spirted over the pelvic area of operation.

The pus sacs were removed together with the uterus, and the abdominal incision was completely closed, without drainage. You will see from the temperature charts that both healed by first intention, and without fever or complications. It was the milk injections that gave us the necessary clue from the point of view of treatment and prognosis. Surely this procedure is worthy of notice and an advance in operative gynaecology.

During the last two years we have had scores of similar cases where the prognosis and operative treatment were made easy by this procedure; moreover it is an interesting fact to record that the recovery of these patients is without storm or stress, and that it is just as useful in cases of *B. coli* and staphylococcal pyosalpinx as in the more usual gonococcal type.

CASE 2.

Name... Mc C.

If pus tubes have been diagnosed, it is our routine to give three or four injections before operating, for thereby the resistance of the patient is raised and the necessity of vaginal drainage negatived.

The out-patient departments of women's hospitals throughout India are crowded with patients suffering from such conditions as we have enumerated above, but owing to the stress upon beds it is not possible to admit all such patients. We particularly refer to such cases as the boggy, fixed, retroverted uterus after labour or abortion, or the case of constant pain with discharge due to cellular infiltration of the base of the broad ligaments or of the utero-sacral ligaments. Until recently these cases had been treated with the time-honoured and time-abused douche and plug, but our experience with milk injections in the out-patient department has shown that this is a treatment far better and more expeditious.

Table showing the nature of cases where milk injection was given and the results thereof:--

	Relieved.	Number cured.	Operation required.	Total.
Tubo-ovarian mass.	13	18	5	36
Retroverted fixed uterus.	4	3	1	8
Trigonitis ..	2	2
Parametritis ..	6	13	1	20
Thickening of utero - sacral ligaments.	6	4	..	10

The criterion of results has been achieved by (a) voluntary statements of the patient,

Case 3.

Name—Raju Bala. Caste Hindu. Age 17.

The following table will show you the type and number of cases treated:—

(b) bimanual examination. If four to six injections of milk or Aolan have been given it is

extremely rare to find other than great improvement; for instance in August 1929 a Bengali patient, suffering intensely from pain in the left thigh, was admitted to the wards of Sir Frank Connor. It was found that she had a diffuse left-sided parametrial exudate extending almost to the left kidney. This condition occurred after a septic miscarriage; she was sent for opinion to the Eden Hospital and six injections at four days' interval were given. She was seen again on September 26th, when the greater part of the parametrial phlegmon was found to have dissolved and the patient herself stated that all her pain, which had been excruciating, had gone and she was now able to walk freely.

Another type of case frequently seen in upper and middle class practice is the old chronic salpingitis, subsequent to gonorrhoea or abortion. These cases, as you are aware, are frequently a source of invalidism, with menorrhagia, leucorrhoea and backache with or without attacks of low fever. Such cases treated up to date with detoxicated vaccines, diathermy or douches and plugs, give disappointing results. If operation is refused, excellent and often lasting cure can be obtained by non-specific protein treatment. It has been said that the proof of the pudding is in the eating, therefore we have no hesitation in recommending this treatment to practitioners in India who see these cases.

Finally, we wish to advise this line of treatment in cases of acute puerperal sepsis, for it would seem to be of greater value than anti-streptococcal serum. For instance, in September 1929 a patient was admitted 24 hours in labour with the arm prolapsed, smelling abominably. She had come 100 miles by train and the uterus was in tonic contraction. Evisceration and decapitation were performed and afterwards 10 c.c. of milk was injected into the buttock and repeated on the second day. Despite the threatened or expected acute puerperal septicaemia, her temperature, beyond the subsequent reaction of the injections, gave no anxiety, and her recovery was uneventful (Case 3).

One must suppose therefore that the protein stimulates the necessary activity of the cells in the cervix and broad ligament which combat infection.

For years we have been urging the adoption by the women's hospitals of India, of the low Caesarean method of De Lee. India is the country *par excellence* in which this operation should be known and practised, for as you are aware, owing to absence, neglect or ignorance of the principles of ante-natal care, the majority of difficult labour cases arrive in hospital or are seen by the private doctor when the membranes have ruptured, and the head is high up and mobile above the brim of the pelvis.

One of the great advantages of the De Lee operation is that it can be done in labour and when the case is septic and the membranes have ruptured, provided the baby is alive. We have

done scores of these operations, and the results are astounding, for whereas a few years ago both mother and child would have been martyrs to ignorance, to-day both are saved.

Why does the mother live in these septic cases, despite opening the abdomen? The reason is that if the operation is properly performed, the incision is in the uterus under the peritoneum, and at the level of the bases of the broad ligaments, which are crammed with guardian cells which deal with any septic spill from the uterus and its incision, when once the peritoneum is efficiently sutured over the area of operation, a drainage tube in such cases being put suprapubically into the utero-vesical pouch. Let us record such a case.

Case.—In August 1929 Mrs. F. was sent into hospital in labour 48 hours; temperature 102°F., pulse 100, the head above the brim and a large child. R. O. P. On opening the lower uterine segment faecal stinking liquor amnii gushed out. A ten and a half pound baby was delivered, which lived and thrived. The spill from the uterus was carefully mopped up, and a suprapubic drain inserted after closing the transverse uterine incision.

The mother recovered completely after a period of fever due to *B. coli* infection. A few years back, when eversion of the uterus before incision was in vogue, this patient would have died of peritonitis. There must be in India every year thousands of very similar cases, where the child is sacrificed to delay or craniotomy, and the mother to rupture of the uterus or the old-fashioned classical incision. Most earnestly we ask the obstetricians of India to consider and do the low Caesarean section in such cases, rather than perhaps sacrifice both mother and child on the altar of ignorance and tradition. For the processes of Nature are there to help us if we will but use them.

Technique of Protein Therapy used in the Eden Hospital:—

(1) Boil four ounces of fresh cow's milk for 20 minutes, and set aside to cool. Using a sterile Record glass syringe the needle is then passed down to the lower one-third of the milk so as to draw up 5 to 10 c.c. of fat-free fluid. This is injected at once into the buttock muscle on a line two inches from and at right angles to, the top of the intergluteal fold. The site of injection is then well massaged and the patient is told to expect a bout of fever and reaction in about 4 hours, which will last 24 hours. The greater the reaction, the better the result.

(2) If cow's milk is not used there is on the market a preparation called Aolan sold in 2.5 and 10 c.c. ampoules, which is handy and saves doubt and trouble. The first injection is 5 c.c. and every four days afterwards 7 or 10 c.c. is given for five or six injections in all. The greater the reaction the better the result.

ON THE ADVISABILITY OF A ROUTINE WASSERMANN REACTION IN EVERY CASE OF DIABETES MELLITUS.*

By H. STOTT, M.D., M.R.C.P.,
LIEUT.-COLONEL, I.M.S.,

Professor of Pathology, King George's Medical College, Lucknow, and Physician to King George's Hospital.

At the Annual British Medical Association Meeting at Manchester in 1929, Professor A. S. Warthin, Director of the Pathological Laboratories in the University of Michigan gave a

* Being a paper read at the Medical and Veterinary Research Section of the Indian Science Congress, Allahabad, January, 1930.

summary of his findings of the lesions of latent syphilis in the various body organs, which have formed his intensive study for the last 23 years and of which he is justly so recognised an authority.

As regards the pancreas, Professor Warthin found that the lesions of latent syphilis were frequent, usually in the form of a mild interstitial pancreatitis not arising from the ducts. Moreover this interstitial pancreatitis was the most common form of pancreatic disease found in diabetic post-mortem material.

To the naked eye, in severe cases the organ was small, and much firmer than normal, except where there was marked œdema of the interlobular stroma, when the organ was usually larger and softer. Professor Warthin therefore believes that this interstitial pancreatitis of acquired syphilis may be one cause of pancreatic insufficiency. He also found that syphilitic pancreatitis with the presence of spirochætes and with varying degrees of fibrosis is frequently of congenital origin, and that this fibrosis may cause pancreatic insufficiency early in life.

These interesting findings of Professor Warthin support the views which we in Lucknow in our diabetic investigations have held and taught for many years past. We believe that even in a fat diabetic of the alimentary type, the insulin producing power of whose pancreas is, in the majority of cases, worn out by prolonged overwork, the superadded factor of syphilitic pancreatitis not infrequently aids in the pancreatic insufficiency. Moreover we find that in our series of 100 cases of diabetes those under 25 years of age showed a definitely higher positive Wassermann rate of 50 per cent. as compared with a positive rate of 32 per cent. in those over 25 years of age, pointing to the fact that the pancreas is affected more often in heredo-syphilis than in the acquired disease, and hence to the fact that syphilis is of special ætiological importance in the more serious type of diabetes of children and of adolescents. Syphilitic brain lesions too may lead to glycosuria—in the same way as any other brain tumour or other brain lesions—i.e., by irritating the region of the floor of the fourth ventricle.

Further, clinically, diabetics under our treatment with a positive Wassermann reaction have improved more rapidly and to a greater extent when placed on anti-syphilitic remedies, than when they were treated by diet and by internal remedies alone. In one case indeed the glycosuria entirely cleared up permanently with anti-syphilitic treatment alone, unaccompanied by any dietetic restriction. The possible danger of giving salvarsan to severe diabetics will be remembered, for one case of syphilis with serious diabetes went into coma after 0.35 gram salvarsan.

The pathological, serological and clinical evidence therefore all point to the importance of a

routine Wassermann test in every case of diabetes. For if this reaction be found positive, the patient will undoubtedly benefit materially if the syphilitic factor, which must unfavourably affect his pancreatic sufficiency, be removed.

DIABETES MELLITUS IN CHILDREN.

By J. P. BOSE, M.B. (Cal.), F.C.S. (Lond.),
*Research Worker on Diabetes, School of Tropical
Medicine and Hygiene, Calcutta.*

Introduction.—There is no doubt that diabetes is much less common in children than in adults, specially in this country, and this is my excuse for publishing this short note on the following case of diabetes in a girl 12 years old. To save space, I have curtailed my notes and have only given a few salient features in the case.

Incidence.—An analysis of 1,025 cases of diabetes at Johns Hopkins hospital showed that only 8 cases among them were children between 1 to 10 years of age (0.78 per cent.), and 68 were of the age from 11 and 20 years (6.6 per cent.). In 1910, Von Noorden recorded only 2.8 per cent. of cases in children among his total of 3,000 cases, and Joslin, in his series of 2,440 cases of true diabetes, found that only 5.7 per cent. among them were children.

Age of onset.—Osler has recorded cases of diabetes under one year old. The youngest diabetic child in the Joslin series is a baby of 8 months old. Ashby (*Lancet*, 1923, i, 22) described the case of a five-months-old diabetic baby with gangrene of the toes. Major and Curran (*Journ. Amer. Med. Assoc.*, 1925, 84, 674) reported a case with diabetic cataract in a baby 11 months old.

In India, the late Rai Bahadur Dr. U. N. Sen reported a case of diabetes aged 6 years; there was a definite history of diabetes in the family and the child suffered from congenital syphilis as well. The youngest case in my series was an acute case of diabetes in an Anglo-Indian boy of 8.

Etiology.—Very little is known about the etiology of diabetes in children. According to many observers, heredity is regarded as an important factor in some cases.

Prognosis.—Is always grave, though there has been a much brighter outlook since insulin has been discovered, which has helped much in making the life of these children comfortable and in prolonging life by regular or periodical routine treatment by judicious adjustment of diet and insulin.

Symptoms, complications and treatment.—These are more or less the same as in the adult cases, except that in prescribing a diet for these children, one has carefully to calculate the caloric requirements of the patient according to his age, remembering that the protein-ration for a child per kilo. of his body-weight should be greater than that of an adult. It should also be borne in mind that children as a rule cannot take the

same proportion of fat per kilo. of body-weight as an adult, and that they are more liable to develop acidosis on a diet in which the proportion of fat is high.

Fig. 1.

Fig. 2.

CASE.

Knmudini, Bengali Hindu female, age 12 years, admitted into the Carmichael Hospital for Tropical Diseases on 23rd June 1929.

Past history.—She is reported to have suffered from some kind of urinary trouble when one year old, the exact nature of which could not be ascertained; no illness since.

Family history.—Clear; comes from a lower middle class; married about 1 year ago.

History of the present illness.—The patient had always enjoyed good health till she was 11 years and 2 months old (i.e., until 2 months after her marriage). From that time, she began to lose weight suddenly and rapidly, and extreme thirst, polyuria and a burning sensation over the whole body appeared within a very short time.

Condition on admission.—(Fig. 1). Very emaciated (almost skin and bone), extremely weak, could not walk, became breathless on the slightest exertion. She complained of a severe burning sensation over the whole body and an insatiable thirst.

Physical examination.—The patient was very undeveloped. The skin was dry and harsh, the tongue dry and raw, the teeth and gums healthy, no enlargement of glands, thyroid not palpable.

Heart sounds normal, lungs clear. No abnormality could be detected on abdominal palpation. No septic foci anywhere could be elicited. Her weight was 44 lbs. (20 kilos).

Laboratory examinations.

Urine.

Sugar	8 per cent.
Acetone	+++
Diacetic acid	++

Blood.

Blood-sugar	0.350 per cent.
Examination for microfilaria			Negative.
Agglutination against Typhoid,			
Para A, Para B, Shiga,			
Flexner	Negative.
Aldelyde test	Negative.
Blood for malaria parasites	Negative.

Stool.

Culture	No non-lactose fermenters.
Protozoa	Blastocystis +.

Treatment and progress of the case.—On account of her very low condition, she was put on a fairly liberal diet, allowing 45 to 50 calories per kilo. of her body-weight. The protein-ration given to her was 3 grammes per kilo. of her body-weight and she was given about 100 grammes of carbohydrates in various forms to start with, the fat-ration being kept fairly low. The diet was then carefully reduced gradually.

The blood-sugar fluctuated between 0.300 per cent. to 0.480 per cent. for some time and eventually came down to 0.210 per cent. near about which level it kept for some time. The quantity of urine passed daily fluctuated a good deal, varying from 40 ozs. in some days to 150 ozs. in others. The maximum quantity of sugar passed was 235 grammes per day. She was put on insulin treatment, first one injection daily, later on twice, the maximum dose given during her stay in hospital being 44 units daily. Under insulin, all the distressing symptoms disappeared quickly, the patient felt quite comfortable and gained in flesh and weight as Fig. 2 will clearly show. The only undesirable symptom which could not be controlled by any method of treatment was her "beg, borrow, or steal" -way of getting all kinds of extra diets from various sources in spite of all precautions. When, at last, very stringent measures were taken and her questionable habits were put under restraint, she and her over-affectionate father got rather annoyed with the strict discipline observed in the hospital and the latter decided to take his ward away in spite of advice to the contrary; he however promised, as usual, to continue the insulin treatment and rigid dieting at home. She was discharged from hospital "improved."

THE TECHNIQUE OF SPINAL ANALGESIA.

By Dr. J. G. MARTIN, M.D.

(Western Reserve Medical, Cleveland, U.S.A.)
American Mission Hospital, Taxila, Pnmjab.

SOME three years ago we began to employ spinal analgesia at Taxila Hospital. We had seen chloroform used in many hundreds of operations in various clinics in India, but were always more or less on edge while operating, lest the anæsthetist should give too much. Further, it has been repeatedly shown that a chloroform anæsthesia of any length causes actual

pathological changes in the liver. Ether on the other hand, although practically fool-proof as far as the immediate anaesthesia is concerned, we have seen end in a pneumonia, and light up an acute tuberculous process in the lungs. Furthermore it is a dangerous anaesthesia to give in a stove-heated operating room, which is the usual source of heat in North India.

We bought the Labat outfit of syringes and needles and used the technique as described in Labat's work on *Regional Anaesthesia*. At first in order to prevent the fall of blood-pressure we used intramuscularly an ampoule of an ether-camphor mixture marketed by Parke, Davis and Co.; when ephedrine came on the market we began to use a $\frac{1}{2}$ gr. of this intramuscularly. Shortly after this Sise, in the *Surgical Clinics of North America*, Vol. 8, p. 195, called attention to the fact that if the neocaine or novocain was given intraspinally before the pressor effects of ephedrine had taken place the ephedrine failed to maintain the blood-pressure. For this reason we began to give the ephedrine just after we had drawn the 10 to 15 c.c. of spinal fluid as described in the Labat technic. In a minute or so after the ephedrine had been given, or by the time the neocaine crystals had been dissolved in some 3 c.c. of the withdrawn spinal fluid, the pressor effects of the ephedrine had taken place. This could readily be seen by the increased rate of flow of the spinal fluid upon withdrawing the stylet from the needle with which the lumbar puncture had been done, and which was in position awaiting injection of neocaine dissolved in spinal fluid.

At first we took the blood-pressure, and followed Labat's contra-indication of not using spinal anaesthesia when the blood-pressure was below 100. But the effects of ephedrine so pleased us, that we no longer used the blood-pressure as an indication for or against spinal anaesthesia, but this anaesthesia became our routine for all operations below the diaphragm. In all we have given some 50 spinal anaesthetics, and in not one of them have we had any reason to feel anxious. In a few cases early in our experience the patients became nauseated. This was quickly relieved by dropping down the head of the operating table. Since we have learned the proper use of the ephedrine, I do not recall a single case where there has been any nausea.

Following the reading of an article in the *Journal of Surgery, Gynaecology and Obstetrics* for November 1929 by Koster and Kasman on spinal anaesthesia for the head, neck and thorax, we have operated upon a man of 60 years with an epithelioma of the eye, in which it was necessary to enucleate the eye. Our technique was as follows. The man was given no previous narcotic or sedative. He was seated on the operating table in the usual crouched-over position for lumbar puncture. One-half grain of ephedrine was given intramuscularly into the deltoid. With a fine needle a few c.c. of $\frac{1}{2}$ per cent,

novocain were injected, first intradermally and then deep in the muscle and fascia between the 3rd and 4th lumbar vertebrae. Through this area a lumbar puncture needle was passed carefully so as not to pass beyond the posterior compartment of the subarachnoid space. For Koster and Kasman have called attention to the introduction of the anaesthetic fluid into the anterior compartment as a probable cause of the sudden fall of blood-pressure, since the anterior roots lie in this compartment and these contain the vaso-constrictor fibres. Eight c.c. of spinal fluid is drawn off in a syringe attached to the lumbar puncture needle. In this was dissolved 0.24 gm. of Neocaine crystals supplied in sterilized tubes by the Anglo-French Co. of 0.10 gm. and 0.12 gm. This 0.24 gm. of Neocaine dissolved in 8 c.c. of spinal fluid was injected into the subarachnoid space through the needle already in position. This needle was withdrawn and the man was placed in a Trendelenburg position of about 15 degrees.* After about five minutes, since the man insisted he was still quite conscious, he was given a few whiffs of ether by placing in his mouth a rubber tube attached to an ether vaporizer used in tonsilectomy. As soon as the tumor had been enucleated the rubber tube was removed and the necessary incisions of his eye-lids made in order to remove the tumor, after enucleation these were sutured, while the patient carried on a conversation with the operator. During this entire procedure the patient's radial pulse was regular and quite palpable. There was no nausea or vomiting. After the operation, the patient was returned to the ward and placed in bed with the foot of the bed slightly elevated. Four hours later the doctor passed through the ward and the patient was sleeping soundly, having as yet received no narcotic or sedative. That evening the patient sat up and enjoyed a good meal.

Koster and Kasman, by showing that the cocaine group of drugs have a selective affinity for sensory nerve tissue and that the respiratory centre appears to have a high immunity, have placed the technique of spinal analgesia on a new basis. Instead of the warning to elevate the head in order that the anaesthetic fluid might not reach the respiratory centre, one must keep the head down, so that the respiratory centre may not suffer from anaemia—the probable cause of death due to spinal anaesthesia.

Koster and Kasman recommend the following dosage. For ordinary anaesthesia up to the diaphragm for a period of 50 minutes 0.10 gm. Neocaine in 4 c.c. of spinal fluid. For thorax and head anaesthesia in children from 7 and 8 years upwards and in adults 0.25 gm. Neocaine in 8 c.c. of spinal fluid. The same in anaesthesia in children from 8 to 5 years, 0.20 to 0.15 gm. Neocaine in 6 c.c. of spinal fluid. Between

*It is understood that this lumbar puncture, etc., has been carried out aseptically, not antiseptically.

the ages of 2 and 5 years, 0.15 to 0.10 gm. Neocaine in 4 c.c. of spinal fluid; and below the age of 2 years. 0.05 gm. to 0.10 gm. of Neocaine in 3 c.c. of spinal fluid.

Here is an anæsthesia that is cheap, safe, causes no pathological changes in tissue, and is the best nerve-block known. It is ideal for the surgeon in that he does not have the worry of an incompetent anæsthetist, he has a quiet patient, who is breathing quietly, with a normal or decreased blood-pressure (which means less loss of blood than under such an anæsthesia as ether) and with a perfectly relaxed voluntary musculature.

HELMINTHIC INFECTIONS IN SHILLONG.*

By A. N. SHARMA, M.B., D.P.H., D.T.M. & H.,
MAJOR, I.M.S.,
Shillong.

Introduction.—Shortly after his arrival in Shillong, the author noticed quite a number of men reporting sick every morning who appeared to him to be suffering from effects of helminthic infections, as most of them complained of general weakness, loss of appetite and disinclination to do any work, whilst others had definite symptoms of colitis and dysentery: a dose of castor oil or magnesia generally resulted in their passing a few round-worms.

Consequently a regular examination of the stools of all troops in the garrison was carried out during the months of September to December 1929. Samples of fresh stools of 503 civilians, consisting mostly of labourers and working classes, were also examined in order to compare the incidence of helminthiasis in the troops with the civilian population as well as to reveal any local foci of infection.

The survey failed in the latter respect.

Note.—Samples of dust from—

- (a) Streets around the regimental lines;
- (b) near the building operations; and
- (c) around the latrines were also collected and examined several times in—
 - (i) dry state, and
 - (ii) in saline—but were found to be negative for helminthic ova.

METHOD.

(1) The method followed was to mix up a small quantity of fæces on a slide with normal saline and to search the whole area under the cover slip first under a 1|3rd objective and later under the 1|6th.

(2) Failing to find any ova, another slide was prepared with Gram's iodine and searched.

(3) If negative again Lane's direct centrifugal flotation method was used—thus it is very probable that only a few helminthic infections were missed, if any.

The total number of stools examined were 1,728, consisting of:—

540	.. 1st Battalion.
685	.. 2nd Battalion.
503	.. Civilians
1,728	

Of these the total number of stools positive for helminthic infections were 1,046, i.e., 60.5 per cent.—thus most of the cases had more than one type of helminthic ova.

NOTE.

(1) It is to be noted that the percentages of infections were more in the 1st Battalion as compared to the 2nd on account of the fact of their having been stationed about a year and a half longer in Shillong—the 2nd Battalion having only arrived here in April 1929.

(2) *Ages.*—The ages of soldiers examined were between 18 and 40, that of the civilians being between 10 and 50.

GENERAL FINDINGS.

(1) A very large percentage of men were found to be suffering from *Ascaris* infection, thus out of a total of 1,728 stools examined 995 were found to contain *Ascaris* ova (see Table I). As a result of a mass treatment of one of the battalions a very large number of adult worms were passed.

(2) *Ankylostoma* is very prevalent, i.e., 22.9 per cent. of the total number examined. It is not surprising considering the system of latrines and the habits of the people as regards ablutions.

(3) *Trichuris trichiura* is quite common, i.e., 13.4 per cent. of the total number.

(4) *Enterobius vermicularis*; it was very surprising to find 47 cases of the ova of this nematode in adults, 2.7 is quite a large percentage.

(5) Eighty-nine samples of stools had *Strongyloides* larvæ in non-infective stage.

(6) The ova of *Fasciolopsis buski* were found in forty cases—this fluke is quite common here, i.e., 2.1 per cent.

(7) *Gastrodiscus hominis* was found in 56 cases; as a result of thymol treatment a large number of cases passed the worms.

(7) It is very interesting to note that four cases of *Heterodera radicola* and three of *Bertiella satyri* were found; only amongst the civilian group.

(9) One case of *Tæmia saginata* was found in a soldier who was serving on the North-West Frontier last year and arrived in Shillong a few months ago.

* Being a paper read at the Medical and Veterinary Research Section of the 17th Indian Science Congress, Allahabad, January, 1930.

The following tables are attached:—

TABLE No. I.

A list giving the number and percentages of various helminths in Shillong out of a total of 1,728 samples of stools examined.

THE VALUE OF THE ANTIMONY TEST IN THE DIAGNOSIS OF KALA-AZAR.

Part II.

THE FINGER PRICK BLOOD TEST.

By R. N. CHOPRA,

LIEUTENANT-COLONEL, I.M.S.,

Professor of Pharmacology,

and

B. P. MUKHERJEE, M.B. (Cal.),

Research Assistant.

(From the Department of Pharmacology, Calcutta School of Tropical Medicine.)

Introduction.—From the time of the discovery of the antimony test for the diagnosis of kala-azar (1927) the great sensitiveness of the reaction was appreciated by its originators. They found that the reaction was obtained in fairly high dilutions of the serum and quite apparent and definite precipitation was obtained in dilutions of 1 in 10 to 1 in 20. Chopra, Gupta and Basu (1927) described a simple test for the diagnosis of kala-azar which could be performed with a drop of blood, obtained from a finger pricked with a needle, and diluted with a solution of potassium oxalate. Although the series of cases of both kala-azar and controls on which this test was tried were small, these workers came to the conclusion that the results obtained with this simple test ran practically parallel with those obtained with the serum test and that the reaction had great possibilities in giving a simple, rapid and economical test for the diagnosis of kala-azar.

Napier (1929) carried out a series of observations with the finger prick test in the Out-patient Department of the Calcutta School of Tropical Medicine and Hygiene but did not obtain satisfactory results. The present authors, therefore, very carefully went into the details of the test and carried out a large series of observations with different dilutions of the blood and the reagent, the diluted blood with corpuscles in suspension

and without. It is unnecessary to describe the details of this work here and we will confine ourselves to some of the salient facts which will help the practitioner to understand and perform this test. Throughout the whole of the research our object was to evolve a simple and rapid test for the diagnosis of this disease. We wished specially to avoid the puncture of the vein to obtain blood so that the test could be carried out by the bed-side or on a large scale in the kala-azar treatment dispensaries in an area where the disease is prevalent. We are very grateful to Dr. L. E. Napier, in-charge of the Kala-Azar Research, for his kindness in giving us access to his patients in the wards of the Carmichael Hospital for Tropical Diseases as well as the Out-patient Department. But for his help and co-operation it would not have been possible for us to carry out the present observations.

TECHNIQUE.

The original technique of this test was published in the August number of the *Indian Medical Gazette*, 1927, and after subsequent observations we have made certain alterations in this technique which is now as follows:

A drop of blood from the pricked finger is received in a small test tube (3/8th inch internal diameter and 2 inches long is most convenient) containing 1/4 c.c. of a 2 per cent. solution of potassium oxalate. If a larger quantity of oxalate solution is used, a correspondingly larger quantity of blood from the finger will have to be taken. The drop can easily be received into the tube containing the oxalate solution by pressing its mouth against the finger with the drop of blood in the centre and inverting the tube. The oxalate solution thus takes up the drop of blood, which is then shaken to get a thorough admixture. The corpuscles are allowed to settle down and this usually takes about 10 minutes or a quarter of an hour. The supernatant fluid is taken by means of a capillary pipette and is transferred to a miniature test tube 4 to 5 mm. in diameter and 2 inches long. A 4 per cent. solution of urea-stibamine is then allowed to run slowly along the side of the tube as in case of the serum test. The heavy antimony solution rapidly permeates through the diluted blood serum and in case of kala-azar blood a coarse flocculent precipitate is seen appearing slowly in the whole column of the fluid. As has been already pointed out in the serum test dilution method, the flocculent character of the precipitate is the true criterion of positivity. A non-flocculent precipitate or haziness in the solution or even a granular precipitate should not be considered as giving a positive reaction. According to the physical character of the precipitate we class the results as follows:—

(1) *Positive reaction.*—Here the precipitation is very definite and its flocculent character is distinct and evident to the naked eye.

(2) *Doubtful reaction.*—In these cases there is usually some haziness after the addition of the

urea-stibamine solution or a granular looking precipitate may be formed, but there is no true flocculation. Sometimes it may be possible to decide this after examination with a magnifying lens but often it is not necessary.

(3) *Negative reaction.*—The fluid remains absolutely clear after the addition of urea-stibamine solution.

TIME FACTOR IN THE FINGER PRICK TEST.

In the series of cases done by Dr. Napier, referred to above, the test was performed in the Out-patient Department and the results were read by the senior author later on in his laboratory. Sometimes an hour or two elapsed before this was done and we were convinced at the time that this was not right and was probably one of the causes of discrepancy in the readings. We therefore decided to work out the time of appearance of the precipitate, its maximum development and any further change which might occur after the solution of urea-stibamine was added to the diluted blood several hours after the test was performed. For this purpose 50 cases of definitely diagnosed kala-azar with positive parasitic findings and 50 non-kala-azar controls were taken and in each case the tubes were carefully examined at regular intervals for 2 or 3 hours after the mixing of the fluids, the results being carefully recorded. The following table gives a summary of the results obtained:

TABLE I.

Time of appearance of flocculent precipitate in 50 definite kala-azar cases in which diagnosis was made by finding L. D. bodies.

Number of cases.	Time taken by the precipitate to become distinctly flocculent in character.
9	1 minute.
15	2 minutes.
12	3 minutes.
12	4 minutes.
2	5 minutes.
TOTAL 50 cases	

39 out of 50 cases in 2 to 4 minutes, in 9 cases in 1 minute, and 2 cases in 5 minutes. In no case did the precipitate take longer than 5 minutes to appear. After this period the precipitate remains in suspension for at least 10 to 20 minutes and then gradually settles down at the bottom of the miniature tube leaving a clear or hazy supernatant fluid. The best time for reading the test from these cases would be between 5 to 10 minutes after the test was performed.

TABLE II.

Time of development of haziness or any kind of precipitate in 50 non-kala-azar control cases.

Number of cases.	Time in which haziness or slight granular looking precipitate appeared.
0	10 minutes.
3	30 minutes.
8	40 minutes.
7	50 minutes.
32	No precipitate or haziness appeared within 50 minutes.
TOTAL 50 cases.	

A perusal of Table II gives the results of observations with 50 control cases. It will be seen that in no case did the flocculent precipitate appear within 10 minutes as in the case of kala-azar sera. In 18 cases out of 50 a haziness or some sort of precipitate appeared in the tube 30 to 50 minutes after the test was performed; 32 remained quite clear even after 2 hours. The readings taken after standing for 20 minutes would, therefore, be fallacious.

It would, therefore, be advisable to take readings within 10 minutes after mixing the fluid, never more than 15 minutes.

FINGER PRICK TEST IN KALA-AZAR CASES.

Table III gives the results obtained with the finger prick test in 124 definite cases of kala-azar in which the diagnosis was made by parasitic findings. The finger prick test, antimony test with diluted serum, and aldehyde test were studied in this series to determine their comparative value.

TABLE III.

	Total number of cases.			Percentage of cases.		
	Strongly positive and positive.	Doubtful.	Negative.	Strongly positive and positive.	Doubtful.	Negative.
Finger prick test	100	11	13	80.7 %	8.9 %	10.4 %
Antimony test. Diluted (1 in 10)	107	8	9	86.3 %	6.5 %	7.2 %
Aldehyde test	105	15	4	84.7 %	12.1 %	3.2 %

A perusal of Table I shows that well marked development of flocculent precipitate occurred in

A perusal of these results shows that the finger prick test was positive in 80.7 per cent. in this

series, as compared with 86.3 per cent. of the antimony test with diluted serum, and 84.7 per cent. with the aldehyde test. The doubtful and incorrect diagnosis in definitely kala-azar cases amount to 19.3 per cent., as compared with 15.5 per cent. with the aldehyde test, and 13.7 per cent. with the antimony test with diluted serum.

Table IV gives results of the test in 162 cases from the Out-patient Department of the Calcutta School of Tropical Medicine and Hygiene in which the diagnosis was made on the basis of the aldehyde test.

positive findings only in 9 cases, or 11.5 per cent., as compared with 6.4 per cent. in the antimony test diluted serum method, and 5.1 per cent. with the aldehyde test. The percentage of "positives" and "doubtfuls" with the finger prick test is 24.4, with the antimony test diluted serum 22.8, and with the aldehyde test 38.4. All these cases were from the Out-patient Department of the Medical College, Calcutta, and the readings of the aldehyde tests were taken by the clinical pathologists of that institution.

When the same test was applied in a non-

TABLE IV.

	Number of cases.			Percentage of cases.		
	Strongly positive and positive.	Doubtful.	Negative.	Strongly positive and positive.	Doubtful.	Negative.
Finger prick test	140	11	11	86.4 %	6.8 %	6.8 %
Antimony test. Diluted in serum (1 in 10)	152	8	2	93.8	5.0	1.2
Aldehyde test	162	0	0	100.0	0	0

A perusal of Table IV shows that the finger prick test is positive in 86.4 per cent. of these cases, as compared with 100 per cent. with the aldehyde test, and 93.8 per cent. with the antimony diluted serum test. The doubtful and negative reactions amount to 13.6 per cent. in case of the finger prick test, as compared with 6.2 per cent. in case of the antimony test with diluted serum. It would not be fair to compare it with the aldehyde test, as in this series this latter test was used as a basis of diagnosis and therefore was bound to give cent. per cent. positive. It will be seen that the finger prick test gives very fair results and should constitute a useful aid in diagnosis where it is not convenient to apply the other more accurate tests.

FINGER PRICK TEST IN NON-KALA-AZAR CASES.

In Table V are given the results of the finger prick test in 78 apparently non-kala-azar cases from a kala-azar endemic area.

It will be seen that the finger prick test gave

endemic area the results were even better. We are very grateful to Dr. P. V. Gharpuré of the Department of Pathology, Grant Medical College, for doing a series of cases for us in the Bombay Presidency.

Table VI gives the results of the finger prick test in 266 cases.

TABLE VI.

Nature of cases.	Total number.	Positive in 1 in 10 and higher dilution.	Negative.
Enlarged spleen	135	2	133
Fevers ..	53	0	53
Malaria ..	64	0	64
Tuberculosis ..	14	0	14
	266	2	264

TABLE V.
Non-kala-azar cases. Total 78.

	Number of cases.			Percentage of cases.		
	Strongly positive and positive.	Doubtful.	Negative.	Strongly positive and positive.	Doubtful.	Negative.
Finger prick test	9	10	59	11.5 %	12.8	75.6
Antimony test. Diluted (1 in 10) ..	5	12	61	6.4	15.4	78.2
Aldehyde test	4	26	47	5.1	33.3	61.6

It will be seen that only 2 cases in the enlarged spleen group gave the characteristically flocculent precipitate. Of these two, one was a suspected case of kala-azar with 18 months' history of fever with anæmia, hydræmia and leucopænia. The formol-gel test was also positive according to Dr. Gharpure's reading but neither a culture nor a spleen or liver puncture was possible. The other patient could not be followed up.

In a non-endemic kala-azar area, therefore, the percentage of negatives with the finger prick test among non-kala-azar cases was 99.3. We have already commented on similar findings in case of the antimony serum test in a previous paper, and the same remarks are applicable here.

DISCUSSION.

The extreme simplicity and ease with which the finger prick test can be performed is its chief asset. The difficulties and dangers of puncturing a vein and drawing blood in non-expert hands are well known. This test, although it is not so accurate as the aldehyde or antimony serum test, will be particularly useful to the medical man working in the endemic kala-azar areas where a large number of cases have to be dealt with and treated. He can form a correct diagnosis in 80 to 86 per cent. of patients as compared with 85 to 95 per cent. by the antimony test with diluted serum and aldehyde test.

SUMMARY AND CONCLUSIONS.

1. The revised technique of the finger prick blood test and the standards of positivity are described. The test is best done with the supernatant fluid after the blood corpuscles have completely settled down at the bottom of the tube. This usually takes 10 to 15 minutes.

2. For the correct interpretation of the test, the reading should be taken preferably from 5 to 10 minutes after the mixing of the solutions, certainly not more than 15 minutes. Readings taken later on are liable to error.

3. In 124 definite cases of kala-azar in which the diagnosis was made by parasitic findings, a positive reaction was obtained in 80.7 per cent. of cases, as compared with 86.3 per cent. with the antimony test with diluted serum, and 84.7 per cent. with the aldehyde test.

4. In 162 cases of kala-azar in which diagnosis was made on the basis of the aldehyde test, a positive test was obtained in 86.4 per cent., as compared with 93.8 per cent. with the antimony test with diluted serum.

5. In 78 non-kala-azar cases, the finger prick blood test gave positive findings in 11.5 per cent. of cases, as compared with 6.4 per cent. with the antimony test with diluted serum, and 5.1 per cent. with the aldehyde test in an endemic kala-azar area. The same test done in a non-endemic kala-azar area in 266 cases gave 99.3 per cent. of negatives.

6. The test is extremely simple, can be rapidly performed, and is a good rough test for the

diagnosis of kala-azar. It is a bed-side test in its true sense. The difficulties and dangers of vein puncture in inexperienced hands are avoided.

A Mirror of Hospital Practice.

A CASE OF SPOTTED FEVER (ROCKY MOUNTAIN FEVER, TICK FEVER OR TYPHUS FEVER).

By S. C. DE, L.M.S.

Acting Medical Officer, Bengal-Nagpur Railway, Bilaspur.

Mr. S., aged 35, Anglo-Indian. Occupation—Guard, Bengal-Nagpur Railway, Bilaspur.

Previous history.—He had no serious illness, except double pneumonia while in Mesopotamia in 1918. He had kept in good health since. No specific history.

trace of albumin in the urine and a large number of the ova of *Ascaris lumbricoides* in the faeces.

I gave her sautonin at bed time and castor oil in the morning with the result that she brought out 962 round worms, one of them through her mouth. On the 4th day I repeated the prescription and 125 more worms came out. On the 8th day the recipe was again repeated with no results. Microscopical examination of the faeces on two occasions showed no *Ascaris* ova. She was discharged from the hospital on the 20th day cured of her insanity and fits. She has been under my observation for the past two and a half months and, I am glad to say, is quite sound in health and brain.

A CASE OF MENINGOCELE.

By A. BAYLEY DE-CASTRO,

LIEUTENANT, I.M.D.,

Military Family Hospital, Hyderabad (Sind).

CASES falling under the spina bifida group are said to occur on an average of one per thousand births, and possibly in big lying-in institutions this average would make their occurrence "rather common," to quote Thompson and Miles.

I had one such case on the morning of the 4th July, 1929, when, after an uneventful labour, a living well-developed girl of 8 lbs. 2 ozs. was born, with an open raw surface 2½ inches long and 2 inches broad in the lumbar region. This raw surface was concave in outline, with the spinal cord clearly visible lying spread out in the middle line.

Palpation revealed a cleft in the vertebral arch, the result of non-closure of the primitive medullary groove. The edges of the wound presented the appearance of normal skin. One very significant fact was that no leakage was observed. The case was diagnosed as meningocele after careful consideration, and was confirmed as such radiographically later on.

I am of the opinion that rupture of the sac took place during delivery, the fluid escaping along with the liquor amnii, but the child showed no signs of collapse and cried vigorously shortly after birth, and also passed urine and meconium. No throbbing was perceptible in the anterior fontanelle on the child crying, and by compressing the wound laterally no bulging was noticed.

The bladder and rectum were not involved, but there was distinct paralysis of the lower extremities.

Two days after birth, i.e., 6th July 1929, the central area of the wound took on a tumorous aspect, which was bluish in colour and was formed by the delicate arachnoid membrane. The edges all around showed healthy epithelialization. On this day it was noticed that the bridge of the nose had fallen in.

On the 15th July 1929 the tension in the sac had greatly increased and sudden rupture with collapse and death being considered possible, the child was put on the seriously-ill list.

By the 19th July 1929 a remarkably tough healthy skin which was growing up from all around was converging to the centre, but as yet three thin bluish areas could be seen.

Trans-illumination showed a translucent swelling without shadow. The edges of the tumour were bony and each ununited spinous process could be definitely felt; the defect involving the 12th dorsal vertebra and the 1st, 2nd, 3rd, 4th and 5th lumbar vertebrae. The child fed well, and was otherwise quite healthy.

On the 30th July the swelling was sterilized with ether and iodine and 6.5 c.c. of cerebro-spinal fluid removed through the peripheral area with a sterile 10 c.c. syringe, the puncture being closed with collodion.

This little operation was carried out on an inclining table with the child's head down. No bad effect was observed. It was discovered at this operation that the tumour was loculated.

On 31st July 1929 the procedure of the previous day was repeated, and 20 c.c. of cerebro-spinal fluid removed. This was done, because (a) there was a slight leakage

of cerebro-spinal fluid at the most prominent part of the swelling, (b) to encourage epithelialization, and (c) to relieve pressure.

A radiograph taken on the 1st August showed the absence of spinous processes, though the laminae were present, i.e., an incomplete neural arch. It also showed a kyphosis in the lumbar region corresponding to the vertebrae where the spinous processes were ununited.

This was no doubt due to the absence of the bracing action of interspinous ligaments which were not acting in the mid-line.

From the foregoing it was apparent that:—

- (a) The condition was one of meningocele.
- (b) The dural lining in the neural canal was deficient posteriorly, and the neural arch incomplete posteriorly through the splaying out of the laminae and non-meeting in the middle line of the spinous processes.
- (c) Through this gap was a hernia of the arachnoid, practically covered with new epithelium growing from the edges.

On the 5th August the tumour had again filled, was very tense, and there was leakage, so another 20 c.c. cerebro-spinal fluid was removed.

The patient was finally transferred to Karachi on the 19th August for further treatment by the surgical specialist, and so I lost touch with her; but I heard subsequently that septic meningitis, which was always dreaded, developed suddenly and finally closed the scene.

The chief features in this case that make it of interest are:—

(1) Absence of hydrocephalus; the absence of bulging of the fontanelle when the child cried, or when the wound was compressed laterally.

(2) Paralytic talipes was totally absent, but a few days before the patient was transferred the big toe of each foot was seen to be flexed on to the sole.

(3) The child was in perfect health and even started to put on weight (9 lbs. 6 ozs.).

(4) The inter-loculated condition of the tumour. Although books do not mention this condition, I think it must be fairly constant if we consider the irregular meningeal adhesions which must occur in such cases.

A SIMPLE METHOD OF TREATING SALIVARY AND OTHER GLANDULAR SWELLINGS.

By F. D. BANA, M.B., M.R.C.S., D.P.H., D.T.M. & H.,
Jun. Hon. Aural Surgeon, J. J. Hospital, Bombay.

It is a well-known fact that enlargements of the pre-auricular gland and the parotid occur as complications of otitis media. The path of infection is evidently *via* the lymph or blood channels, and apart from the pain of acute otitis, there is much swelling and pain in front of the ear. If the mandibular joint is involved and in little children the fright of opening the mouth either for swallowing or for examination, completes the misery of the patient. It is rare for these two structures to suppurate when pus can be let out on incision, but I have noticed as in the following two cases that speedy relief can be obtained from both the swelling and pain by the simple expedient of sterile puncture. A 5 or 10 c.c. syringe with a sharp stout needle is sterilised and the needle pushed into the most prominent part

of the swollen gland after washing the skin with lysol and painting with liniment of iodine. One does not expect nor find pus, but there is withdrawn as much of the serous, or sero-sanguinous fluid, or even blood, as can be drawn by withdrawing of the piston. If the glandular swelling is very tense and hard no fluid can be withdrawn, in which case the needle should be dug in at various points as in exploring an abscess till some fluid can be removed. This is quite a simple procedure, but has given very striking results in the following two cases.

Case No. 1.—Master T., aged 7, was brought to me by the mother for swelling of the right parotid gland for 4 days. The pre-auricular gland was also enlarged. Beyond a little rapid pulse the boy did not complain of fever but of slight pain and fullness in front of the ear and inability to chew his food. No fluctuation was felt, the gland being very hard and tender. Evidently there was no pus formation. There was inflammation for which there was going to be a fight between the bacterial agent or toxins and the boy's defensive powers. But the actual battle had not been fought and there were no casualties in the form of pus or necrotic tissue. I was disinclined to interfere at this stage. So the usual time-respecting remedies were given, salicylates by the mouth and application of glycerine of belladonna locally. Asked to report after four days, there was no change one way or the other, but the swelling had increased. There were no signs of otitis, either of the external meatus or the tympanic cavity, or any inflammation. The membrane looked normal with no pain, nor ear-ache. The only way of explaining the enlargement of the parotid and the pre-auricular gland lay in bacterial infection from the mouth. (The tonsils, teeth and pharynx were apparently healthy.) It was now decided to interfere and I aspirated the pre-auricular gland and the parotid swelling by withdrawing a little fluid at a time, which was sero-mucus in type with hardly any blood in it. A sterile dressing was applied. Within 8 days the swelling completely subsided, at first slowly then later on rapidly and the boy was all right within a fortnight. I dare say if there had been no active interference, the swelling would have subsided of its own accord as soon as the defensive mechanism of the boy had been brought into play, but the question is, after how long? It would have been anything up to a month or two, and meanwhile the patient would have had to endure the inconvenience of a swelling, and pain and fear at mastication, and would have lost weight. Anyway it hastened the progress and lessened the duration of the treatment.

Second Case.—M. F., male, aged 45. A well-known Persian traveller, just returned from a rather tiring sojourn in Seistan, the south-east corner of Persia, presented himself with a history of being run down and having a number of boils on the arms and nose. The boils had been coming on for the last 15 days, first noticed in Karachi, but would not come to a head or burst. They were hemispherical, red-looking lumps, the size of a rupee and not very tender to touch. The one on the tip of the nose showed a point of pus which was incised and carbolic ointment applied. An injection of a 100 million dose of staphylococcal vaccine was given. Four days after the boils were just the same. Another injection of 150 million was given. On the 8th day a sudden swelling on the left side of the jaw appeared. It was a swelling of the sub-maxillary gland which was stony hard to touch, accompanied by oedema of the subcutaneous tissues over the left side of the jaw, neck and cheek. The patient, usually a strong athlete, seemed to be very nervous and anxious to know if the swelling would necessitate incision or operation. I assured him that neither was needed and suggested needling and withdrawal of fluid which in this case was sero-sanguinous. I removed about 1 c.c. of the fluid from the sub-maxillary gland and dressed it aseptically, giving 100

million of a staphylococcal vaccine. Within four days the swelling had diminished and blockage oedema gone. Within the next 10 days the swelling had vanished and the rest of the boils had also healed up.

In this case as well, one can say that the rapid diminution of the swelling was due to the vaccine which I believe was certainly helpful to a degree, but I maintain that the puncture helped this procedure at a critical time and once the pressure of inflammatory tissues was relieved the stewing in its own juice of the inflammatory products was stopped, the immunity rising rapidly. The puncture by itself is not curative. It mainly helps to lessen the duration of the attack on the organ and of pain, and gives speedy relief to the patient. This is the point which I wish to emphasise here, and if other surgeons would try the effect of puncturing at an early stage any tight glandular swelling say of the parotid in mumps and early buboes before suppuration, I believe a lot of relief from pain and swelling could be afforded and progress hastened.

A NOTE ON THE USE OF ULTRA-VIOLET RAYS IN THE TREATMENT OF LEPROSY.

By JYOTI DHUR-ROY, B.Sc., M.B. (Cal.),
and

A. RAKSHIT, B.Sc., M.B. (Cal.).

(From the Department of Radiology and Physiotherapy,
The Chittaranjan Siva Sadan, Calcutta.)

THE success following the use of ultra-violet rays (hereafter mentioned as the "U-V rays") in the treatment of chronic skin diseases, prompted the writers of this note to try U-V rays in the treatment of the skin lesions of leprosy. Though the aetiology, epidemiology and pathology of leprosy are quite different from those of most skin diseases and diseases with cutaneous stigmata, we were determined to see if any change in the clinical course of the disease could be brought about by the judicious use of U-V rays in the dermal lesions due to leprosy.

After its use in a few cases of leprosy, we were really surprised to note the wonderful changes which U-V rays brought about in the skin lesions. We searched in vain the current literature for further guidance in our work; there is no available reference regarding the use of U-V rays in the dermal lesions in leprosy. The use of U-V rays is invariably followed by gradual disappearance of the mutilating and unsightly skin lesions, which are replaced by healthy-looking skin and there is clinical cure of the condition, so far as the skin lesions are concerned. Our leprosy cases, up to now, have been so few in number that we cannot at present give any final opinion on the place of U-V rays in the treatment of leprosy, but we believe that it is worth giving them a trial. U-V rays have proved so useful in our hands in this hospital that we publish this preliminary note with the hope that workers in this field will give it a trial. We do not claim U-V rays as the only specific for the cure of leprosy; what we do claim is that

U-V rays are as useful and essential in the treatment of leprosy as is potassium iodide (though not a specific, like arsenic in the treatment of tertiary syphilis).

In order to see whether the disappearance of the skin lesions is due to U-V rays only (and not due to any drugs) we did not give any drugs, whether specific for leprosy or not, in our last case (mentioned below) who was treated with U-V rays only and hygienic mode of living. We found the result to be excellent as before.

Our Technique of U-V Ray Treatment.

In all our cases, we give two to three minutes' exposure of U-V rays from a quartz-mercury-vapour lamp (Hanovia Standard Model) from a distance of thirty inches. We give the following course of treatment daily, as a preliminary preparation of the patient for U-V rays exposures. The patient is first given a simple water enema; he is then given a general massage of the whole of his body, and a steam bath, which is followed by a cold faradic current plunge bath. The patient is then exposed to the radiant heat rays of the Sollux lamp (Oeken Model), until he feels a little warm, when he receives the U-V rays.

Last case (mentioned above):—

Mr. I., aged 18 years, a student of the Aligarh University, a frank case of leprosy, was admitted on 2nd September 1929 in the out-patients' department of the hospital with the following complaints:—

Macular, depigmented, anæsthetic (leprotic) patches distributed over the skin of the following parts, anterior aspect of the left thigh, around the left knee-joint, side of the left leg, dorsum of the left foot, right leg and right foot, back of left wrist and of right hand. Duration, 4 months.

Contracture of left lower extremity at the knee-joint, resulting in its fixation at an angle of about 90 degrees. Mobility of the joint (flexion and extension) limited to 6 degrees only. Duration, one month and a half.

Constant and severe neuralgic pain along the course of the distribution of the sciatic nerve and its branches, for the last 3 months, for which the patient was having morphia, gr. $\frac{1}{2}$.

Family history.—There is no history of leprosy in his family.

Past history.—The patient does not remember to have come in immediate and intimate contact or association with any frank case of leprosy. He cannot trace the origin of his trouble.

History of present illness.—Six months back the patient took a bath in a shallow village tank. Next day he noticed swelling of his lower extremities, which disappeared in a few days. The patient was having irregular fever, off and on, since then. Since then the patient has had swollen inguinal glands (especially on the left side). Four months ago the patient noticed the anæsthetic patches, which first appeared on the right leg and then extended to other parts of the body in a couple of days, and neuralgic pain for the last three months. The patient can neither flex nor extend his left leg for the last one month and a half.

Present condition of the patient.—The patient is in what is called Muir's reactionary or inflammatory phase of leprosy, i.e., the stage when heroic treatment with active remedies may cause exacerbation of the disease. The distribution of the lesions is mainly on the extensor surfaces of his extremities. The patient can walk only with the help of crutches on account of the contracture of the left knee-joint and pain along the course of the distribution of the sciatic nerve and its branches.

Physical examination.—Symmetrical distribution of large, macular, depigmented, anæsthetic patches, with slightly raised margins, which are of ring-form (like those of ringworm). The skin is glossy, dry, and parchment-like with local thickening. Contracture of the left knee-joint, which is flexed at right angles. Mobility of the joint is limited to 6 degrees only. There is inflammation (sciatic neuritis) of the sciatic nerve and its branches, resulting in severe neuralgic pain in the left lower extremity. The inguinal glands are swollen. Trophic changes in the muscles and skin present. As the case is a frank one of leprosy no micro-section was done.

Diagnostic points.—(1) Depigmented, anæsthetic, cutaneous patches. (2) Thickened skin, which is dry, glossy and parchment-like. (3) Severe neuralgic pain showing inflammation of the sciatic nerve and its branches. (4) Fever off and on. (5) Contracture.

Treatment.—The same technique of U-V rays exposures, as outlined above for 35 days and passive movement and massage of the affected limb (knee). No drugs were given, either by the mouth or by injection. Diet was restricted to fresh fruits and sufficient quantity of fresh unboiled milk or its different preparations.

Result of treatment.—All skin lesions have disappeared completely; the skin looks like that of any healthy man and is free from any stigmata of leprosy. There is complete flexion of the knee-joint and the extension of the joint has improved considerably, though it is not yet complete and normal. Pain has improved a lot.

In conclusion we take this opportunity to thank our Chief, Dr. Ajit M. Bose, M.B., Ch.B. (Edin.), L.M. (Dub.), the Medical Director and Radiologist-in-charge, for giving us all possible facilities in the carrying out of this investigation.

(Note.—According to the writers the patient was in a state of reaction when he came under treatment and the improvement described above would probably have followed in the natural course of events, as the reaction passed off, even if no treatment had been given. No mention of improvement in nerve lesions, such as anæsthesia, is made, nor does a bacteriological examination appear to have been done. Furthermore, no details are given of the results of the treatment in the other cases.—EDITOR, I. M. G.).

A FOREIGN BODY IN THE PERITONSILLAR SPACE.

By RADHA KRISHNA GROVER, B.Sc., M.B., B.S.,
Medical Officer, Garukula-Kangri, District Saharanpore.

A boy, Satya Bhosan, aged 12, felt great discomfort in his throat immediately after taking his meals. There was great retching and nausea, but no vomiting. The boy began to feel pain in the prelararyngeal region. My assistant saw the boy but could not find out the cause of the pain. I was consulted but I also was unable to express a definite opinion. While examining the throat I noticed something white and worm-eaten in appearance protruding in front of the fauces. I took hold of it with a pair of forceps and gently pulled it. To my surprise it came out. It was a bit of a loaf of bread about an inch long. Directly it was taken out, the pain and discomfort disappeared and the boy looked much relieved.

The peritonsillar space is, I think, an unusual site for a foreign body.

Indian Medical Gazette.

APRIL.

THE ACTION OF EMETINE ON *ENTAMÆBA HISTOLYTICA*.

THE medical practitioner in the tropics who is called upon to treat a case of chronic intestinal amœbiasis is faced with considerable difficulties, owing to the number of "amœbicides," "cures," and "specifics" for this condition which claim his attention. The "tests" to which these remedies have been put have usually consisted of examination of a few stools during or just after the cessation of treatment with the drug, and any laboratory worker of experience knows the valuelessness of such a procedure. An immediate disappearance of *E. histolytica* from the stools whilst the patient is under treatment is almost the rule with present-day remedies, whilst the stools frequently give "negative" results for a week or two after cessation of treatment; examination of stools in the third or fourth week after treatment, however, only too often shows that the "cure" has been a temporary one.

Under these circumstances, it is a pleasure to review a recent series of papers from the National Institute for Medical Research, London, by Mr. Dobell and his colleagues, distinguished by the most painstaking, careful, and laborious research, which summarise, once and for all, what is the action of emetine on *E. histolytica*. Taken together, the five papers constitute a symposium on the subject which every worker interested in tropical medicine should read in the original.

The first of these memoirs, by Dobell, Jepps and Stephens (1918) indeed dates back to the period of the Great War.* One hundred and fifty-five persons suffering from infection with *E. histolytica* were treated by a course consisting of 3 grains a day of emetine bismuth iodide orally for 12 days. The criterion for cure was that after the cessation of treatment one stool in the first week, one in the second week, and four in the third week, should give negative findings. In no case was a relapse detected later than the end of the third week, and the authors consider the above standard of six examinations, of which four are to be made in the third week after the cessation of treatment, to be reliable.

*In their review of the literature on the treatment of intestinal amœbiasis, Knowles, Das Gupta, Dutt Gupta, and Gupta (1928) unfortunately omit all reference to this memoir. They did not even know of its existence until their attention was drawn to it subsequent to the publication of their article.

Of 59 individuals who showed relapses, 46 of the relapses were detected during the first two weeks after the cessation of treatment, and 13 during the third week.

The first course of treatment consisted in all of 36 grains of emetine bismuth iodide in 12 days; and 121 out of the 155 patients, or 78.1 per cent., were cured. The most successful results were obtained by administration of the drug as an uncompressed powder in gelatine capsules; by this method 90 per cent. of cases were cured with a first treatment.

The 33 patients who relapsed now all received a second similar course of treatment (Table 5 of the memoir). Twenty were cured,—60.0 per cent., and 12 remained uncured. Of these, 10 received a third course of treatment, after which 2 more were cured. A residuum of 3 uncured patients received a fourth course of treatment, but still showed *E. histolytica* present.

The authors conclude that "a full course of treatment (36 grs.) with emetine bismuth iodide administered in its most suitable form will free the majority (probably about 90 per cent.) of carriers of *E. histolytica* of their infections. Of those cases which remain uncured after such an original course of treatment, a further number can be cured by the subsequent administration of a larger quantity of the drug. But even a quantity of the drug (72 grs.) equal to twice that originally given will not cure every carrier of his infection. There is, however, no evidence to show that the proportion of "incurable" cases is greater than 5 per cent. of all infected cases.... When cases remain uncured (after the first treatment) the best method of re-treating them is to give them a double course of the drug (3 grains daily for 24 consecutive days—72 grains)."

The thoroughness with which these patients were examined after treatment is without parallel anywhere else in the literature, as may be gathered from the following table:—

95	patients	gave	6	negative	examinations	each.
34	"	"	7	"	"	"
3	"	"	8	"	"	"
5	"	"	9	"	"	"
2	"	"	10	"	"	"
1	"	"	12	"	"	"
1	"	"	14	"	"	"
1	"	"	15	"	"	"

The patients treated in this large series were British soldiers, who would presumably withstand larger doses of bismuth emetine iodide than could be administered to weakly Indian patients. The authors note that "although most patients suffered discomfort during treatment, none displayed any serious constitutional symptoms; and almost without exception the patients stated, two or three weeks after treatment, that they felt very much better.... When vomiting occurred it was usually two or three hours after the administration of the double iodide, and it did not persist for more than a few hours. It

did not interfere to any great extent with the night's rest, and the patients usually had excellent appetites throughout the day. Diarrhoea usually began about the fourth day of treatment, and generally ceased about two days after its termination. Cases suffering from chronic gastritis did not appear to suffer any greater inconvenience than the others."

It is not likely that opportunities for so exhaustive and so careful a clinical study, where convalescent troops can be kept under daily observation for weeks together, will recur; and it is largely upon this memoir by Dobell, Jepps and Stephens that the routine use of bisulphate of emetine iodide for the treatment of carriers rests.

With the introduction of cultural methods for *E. histolytica* in 1924, it became obvious that it would be possible to test the action of emetine on *E. histolytica* in culture. This was carried out in an extensive piece of experimental work by Dobell and Laidlaw (1926). Their conclusions were as follows:—

(1) Emetine and cephaeline have been found to be specific poisons for *Entamoeba histolytica* under cultural conditions.

(a) For this amoeba (in culture) these alkaloids are at least fifty times as poisonous as isoemetine, psychotrine, methylpsychotrine, demethoxyemetine or noremetine.

(b) For this species also emetine has been found to be about ten times as poisonous as Stovarsol, and about fifty times as poisonous as quinine—under identical conditions of experiment.

(2) *Entamoeba coli*, *Entamoeba gingivalis* and *Endolimax nana* have been found comparatively insensitive to the presence of emetine in cultures—*E. coli* being able to withstand a concentration of the alkaloid at least one hundred times that which is lethal to *E. histolytica*.

(3) The effect of solutions of emetine on *E. histolytica* are peculiar. Very strong concentrations (1 per cent. or more) are needed to kill this parasite instantaneously; but only very weak solutions (1 in 50,000 or less) are necessary to kill it if allowed to act for a sufficient time.

(4) In view of these findings it is concluded that the curative effects of emetine in human amoebic dysentery are best explained as a result of the direct lethal action of the alkaloid on *E. histolytica*.

This last point needs emphasis, as previous workers had held that the action of emetine on *E. histolytica* was an indirect one. Thus Dale and Dobell (1917) held that the action was an indirect one, basing their opinion chiefly upon the difference of action of emetine in man and in the cat; in man amoebic dysentery is rapidly checked by the administration of emetine; on the other hand administration of emetine to a cat suffering from amoebic dysentery does not influence the course of the disease, which is neither checked nor cured.

Sellards and Leiva (1923) claim that intra-rectal administration of emetine will prevent the development of amoebic dysentery in experimentally infected kittens, but this hardly amounts to the same as cure of an established condition of amoebic dysentery in the animal. It is possible, write Dobell and Laidlaw, that in the cat emetine is rapidly excreted by the kidney, and not sufficient of it reaches the colon to affect the *E. histolytica* infection; on the other hand, in man some of the injected emetine must be excreted into the colon, for its action upon the amoebae is very marked; its ultimate elimination is by the kidney over a period of some five to nine weeks.

Further, conclude Dobell and Laidlaw, the action of emetine on *E. histolytica* *in vitro* is so specific that the utmost caution must be exercised in drawing conclusions from experiments with emetine on free-living amoebae and other protozoa. "Emetine has a specific action upon *E. histolytica* in culture; and in this sense the alkaloid may perhaps be termed "amoebicidal." But it is also clear that emetine is not "amoebicidal" to amoebae in general—or even to all entozoic amoebae—since very strong solutions are necessary to influence the growth of some species. Moreover, the striking differences between the effects of emetine upon two such closely related species as *E. histolytica* and *E. coli* make it obvious that earlier results, obtained by similar methods but with cultures of more distantly related free-living species, are of very dubious significance. From the observed effect of the alkaloid upon one species it is clearly impossible to predict its action upon any other."

In their 1926 paper Dobell and Laidlaw did not pay attention to the possibility of adsorption of emetine from the fluid of the culture medium by the inspissated serum of the medium. This point appears to have occurred to them later, and it was fully investigated by Laidlaw, Dobell and Bishop (1928). They point out that recent workers, in publishing results, have used many different types of media; they often fail to give the necessary detailed data with regard to such matters; and their results are accordingly widely divergent and cannot be compared with one another. Having worked out a method for the detection of very small amounts of emetine, the rate of adsorption of emetine from the fluid to the solid portion of the culture media was investigated. It was found that with Boeck and Drbohlav's medium much more emetine is adsorbed by the coagulated egg portion of the medium, than is the case with the inspissated serum used in Dobell and Laidlaw's HSc + S medium.

This finding made it necessary to test the action of emetine on cultures of *E. histolytica* in entirely fluid media. The first tests were carried out on cultures in inactivated horse serum, diluted 1:8 with Ringer's fluid, and a little sterile rice starch added. Four different

strains of *E. histolytica* (one human and three simian) were tested, and it was found that emetine proved lethal to *E. histolytica* at dilutions up to 1:750,000. The end point, however, was not always sharp, and it was discovered that the final pH of the culture profoundly affected the minimal lethal concentration. The reaction of the fluid was therefore stabilised by adding 0.2 per cent. disodium hydrogen phosphate to the Ringer's fluid used, and adjusting the pH to 7.2. With this results were much more uniform; three of the four strains tested were killed by emetine at a dilution of 1:5,000,000; in the fourth case the culture became unduly acid, pH 6.2, and emetine proved lethal only in dilutions up to 1:750,000.

This paper is of very great importance to all

dysentery is probably due to the direct toxic action of the alkaloid upon the amœba.

The fourth memoir of the series, by Dobell (1929) with the co-operation of Dr. Ann Bishop, deals with the eradication of *E. histolytica* infections in *Macacus* monkeys. As Dobell has shown in previous papers every *Macacus* monkey which he has studied is infected with a parasite which he considers to be identical with *E. histolytica* of man. One of the greatest merits of this very fine piece of work is its detailed account of Mr. Dobell's methods of handling and dealing with his monkeys. Five animals were concerned, and had been under continuous—practically daily—examination and observation of stools for periods varying from 1½ to 4¼ years. They were as follows:—

Name.	Species.	Sex.	Age (years).	Weight (kg.).	Intestinal protozoa.
Polo ..	<i>M. sinicus</i> ..	M.	4	4.91	<i>E. histolytica</i> , <i>E. nana</i> , <i>Giardia</i> sp., <i>Enteromonas</i> , sp.
Jacko ..	<i>M. rhesus</i> ..	M.	4	11.65	<i>E. histolytica</i> , <i>E. nana</i> , <i>Giardia</i> sp., <i>Enteromonas</i> , sp.
Mungo ..	<i>M. sinicus</i> ..	M.	4	4.75	<i>E. histolytica</i> , <i>E. nana</i> , <i>Giardia</i> sp., <i>Enteromonas</i> , sp.
Susanna ..	<i>M. sinicus</i> ..	F.	5½	4.76	<i>E. histolytica</i> , <i>E. coli</i> , <i>E. nana</i> , <i>Giardia</i> sp., <i>Enteromonas</i> , sp.
Rosa ..	<i>M. rhesus</i> ..	F.	2½	4.13	<i>E. histolytica</i> , <i>E. coli</i> , <i>E. nana</i> , <i>Enteromonas</i> , sp.

workers engaged on similar problems, for it shows how very important may be the influence of such overlooked factors as the pH or the composition of the culture medium employed. The authors conclude as follows:—

1. When emetine is added to complex culture-media containing solid and liquid portions it becomes unequally distributed between the two constituents.

2. The distribution between the solid and liquid varies with (a) the nature of the solid, (b) the reaction of the system, and (c) the time.

3. An erroneous idea of the absolute toxicity of emetine for *E. histolytica* is obtained from a consideration of the results with such media (e.g., the egg-serum medium of Boeck and Drbohlav).

4. With a simple (liquid) medium it has been shown that a solution of emetine 1 in 5,000,000 is lethal for all amœbæ (*E. histolytica*—4 strains) *in vitro* within 4 days, provided that the medium does not become too acid.

5. This great potency of emetine *in vitro* may be altered by a comparatively small variation in the reaction of the culture-medium.

6. These results confirm the view that the therapeutic efficacy of emetine in human amœbic

Treatment was with bismuth emetine iodide by the mouth, since this had been found previously to give very much better results than the hypodermic or intramuscular injection of emetine. The double salt was made up in a 4 per cent. suspension in a strong solution of cane sugar in water, and the measured dose administered by a pipette. The doses were given just before the mid-day meal. The giving of the meal immediately after the dose of emetine bismuth iodide distracted the monkey's attention from what he had swallowed, and ensured that the dose given was retained. The fæces were collected immediately they were passed, cultures for *E. histolytica* were taken within a few minutes, and the stool emulsions made and microscopically examined whilst the material was perfectly fresh.

The experiments conducted fall into two series. To begin with, the author had no data to go upon with regard to the toxicity of emetine for *Macques*, or as to how they would tolerate it. Further, it was desirable to carry out the first series of experiments with monkeys who showed no *E. coli* infection, for it is sometimes impossible to assign an individual amœba encountered in the trophic phase with certainty to either *E. coli* or *E. histolytica*. Accordingly the first three animals were selected.

First Series of Experiments.—These may be briefly outlined as follows:—

Polo.—Given 20 mgms. of B. E. I. daily for 22 days; total 0.44 gm. Examinations and cultures positive.

Result; failure.

Jacko.—Given 20 mgms. the first day, followed by 40 mgms. daily for 25 days; total 1.02 gm.

Examinations and cultures positive.

Result; failure.

Mungo.—Given 20 mgms. daily for 24 days; total 0.48 gm. Examinations and cultures positive.

Result; failure.

Although this series of treatments failed to eradicate the infections, yet they showed that monkeys of genus *Macacus* could stand the doses of bismuth emetine iodide given. The only one who showed any symptoms was Jacko, who became dull and listless towards the end of the course of treatment. All of them ceased to grow, however, and the normal increase in weight did not occur. They recovered very rapidly when the drug was discontinued.

Re-treatments.—As the dosage had proved too small to be efficacious in the first set of experiments, all three monkeys were next re-treated with larger doses. Details were as follows:—

Polo.—Given 40 mgms. a day for 15 days; total 0.6 gm.

Culture positive on the 4th day after cessation of treatment.

Examination positive on the 5th day after treatment.

Result; failure.

Next, given 60 mgms. daily for 7 days; total 0.42 gm.

Subsequent cultures and examinations negative for 26 days.

Result; cure.

Jacko.—Given 60 mgms. daily for 11 days; total 0.6 gm.

Examination and cultures positive on the 5th day after cessation of treatment.

Result; failure.

Mungo.—Given 40 mgms. daily for 5 days; then 60 mgms. daily for 13 days; total 0.98 gm.

Examinations and cultures negative for 30 days after cessation of treatment.

Result; cure.

Second Series of Experiments.—As it now appeared that treatment with a daily dose of 60 mgms. was likely to bring about eradication of the infection, and as the monkeys could just withstand this dose, the last two animals were now treated with this dosage. Details were as follows:—

Susanna.—Given 60 mgms. daily for 6 days; total 0.36 gm.

Examinations and cultures negative for 66 days after completing treatment.

Result; cure.

Rosa.—Given 60 mgms. daily for 7 days; total 0.42 gm.

Examinations and cultures negative for 66 days after completing treatment.

Result; cure.

It is clear from these experiments that an infection with *E. histolytica* in a *Macacus* monkey of about 5 kilogrammes weight can be eradicated by about one week's treatment with 60 mgms. of bismuth emetine iodide daily.

On the other hand, such a dosage is not free from symptoms in the monkey. Marked loss of weight was the most striking feature of the experiments, though when the treatment was stopped all the monkeys soon made good the loss in weight. Rosa was the only one of the five who failed to show symptoms of poisoning. Vomiting, diarrhoea, retching, salivation, yawning, and dermal irritation were the chief symptoms. Jacko, the heaviest animal of the series, showed as severe symptoms as any of the animals. On the other hand, all the monkeys recovered condition very rapidly when treatment was stopped, though some of them took a month to regain their normal weight.

It is perfectly clear from these experiments that infection with *E. histolytica* in *Macacus* monkeys can be eradicated by a sufficient course of treatment with bismuth emetine iodide. Now the weight of an average Indian male adult is given in the 8th (1928) edition of Lyon's *Medical Jurisprudence for India* as 110 lbs. (approximately 50 kilos); and the dosage given to these monkeys to eradicate the infection would correspond to approximately $9\frac{1}{4}$ grains daily for an Indian male adult of ordinary weight; or to about 11 grains daily for an average adult male European. Such a dosage would undoubtedly prove toxic to man, though recovery after one week's treatment might be as rapid in man as in the monkey.

The bismuth emetine iodide had no action at all upon the other intestinal protozoal infections affecting these monkeys; these findings corresponding with what occurs in man also. This fact appears to confirm both the previous finding that the action of emetine is a direct and specific one on *E. histolytica* only of the entozoic amœbæ, and that *E. histolytica* of man and of the monkey are identical.

Hitherto "tests" for the "curative" action of any remedy in chronic intestinal amœbiasis have usually consisted in administering the drug for a few days, and examining a few stools either during or just after treatment. The memoir under consideration fully proves the uselessness of such a procedure as a test for eradication of an infection with *E. histolytica*. Dobell goes on to suggest that the natural

infections of *Macacus* monkeys may afford a suitable means for the proper testing of any proposed remedy. "In my experience" he writes, however, "macaques are not easy animals to use for experiments. They require individual personal attention, and can be successfully employed for drug-testing only by workers who are able and willing to devote months—or even years—to their care and study. I say this lest anyone might wrongly infer from the foregoing remarks that I am advocating the study of assorted chemicals upon "amœbæ" in "monkeys" by inexperienced workers. The reverse is my intention. I do not advise anybody to study the action of any drug upon any amœba in any monkey before he has familiarized himself with all the animals concerned, and I would warn him that this is far more difficult than it may appear at first sight..... I am nevertheless firmly convinced that advance in chemotherapy is not likely to occur—save by accident—through random experimentation with drugs of unknown and unpredictable activity, and with "tests" of "protozoa" in general. No discoveries of any practical importance to sufferers from amœbic dysentery are likely to result from crude trials made with speculative compounds upon free-living amœbæ of inaccurately determined species, upon *Paramacium*, or upon other organisms only remotely related to *E. histolytica*. To me it seems infinitely more probable that progress will ultimately be made by carefully calculated attacks from positions already consolidated than by raids into unknown territory from insecure advance-posts."

As the author asks for criticisms, there is perhaps one point that the reviewer may be permitted to raise. The memoir by Laidlaw, Dobell and Bishop (1928) in itself,—and quite independently of the well-known work of Acton and of Sinton on the increased efficacy of quinine salts in malaria, when abundant alkalies are administered orally with them—shows the importance of the reaction of the substrate in which such an alkaloid acts. Daily doses of 11 to 13 grains of bismuth emetine iodide are too risky to use in man (though it must be admitted that the author does not suggest so heroic a dosage for man). Would it be possible to secure equally satisfactory results by using smaller doses, combined with the administration of large doses of alkalies? In all probability the action of emetine on *E. histolytica* is that of emetine base rather than of any emetine salt. The experiment at least would appear to be worth trial.

The last memoir in the series is one by Miss Bishop (1929) on the action of emetine on cultures of *Entamœba coli*. Two strains of this parasite were used; a strain from the above monkey Rosa, after she had been cured of her *E. histolytica* infection by treatment with emetine, and a simian strain experimentally established in man. The cultures were put up in (a) horse serum diluted 1:8 with Ringer's fluid,

but not buffered; and (b) in horse serum diluted with phosphate-Ringer's fluid 1:8. Solid rice starch was used in both media. The author's findings are as follows:—

(1) Two pure strains of *Entamœba coli*, differing in their bacterial flora, and experimental history, but identical morphologically, have been tested with emetine hydrochloride *in vitro*.

(2) In a buffered and wholly liquid medium, with a pH varying between 6.8 and 7.2, emetine hydrochloride was found to be toxic to *E. coli* in dilutions between 1:300,000 and 1:600,000, the toxicity increasing with the alkalinity of the medium.

(3) It is therefore concluded that emetine is about sixteen times as toxic *in vitro* to *E. histolytica* as to *E. coli*.

It is not likely that any drug suggested for the treatment of intestinal infection with *E. histolytica* will ever undergo as thorough an experimental trial as has bismuth emetine iodide at the hands of Mr. Dobell and his colleagues. The work is complete, exhaustive, and satisfactory. The conclusion to be derived from it is that in bismuth emetine iodide,* we possess a really efficient agent for the eradication of intestinal infection with *Entamœba histolytica*. On the other hand, unfortunately the drug has to be given in almost toxic doses if the infection is to be completely eradicated. Perhaps the most important conclusion in the work is that the action of emetine on *E. histolytica* is a direct and not an indirect one. This may afford food for reflection to the school of experimental workers who propound the view that the action of all drugs in protozoal infections of man is an indirect one, and that protozoal parasites of man cannot be directly attacked by any drug.

SPECIAL ARTICLES.

A REVIEW OF SOME OF THE WORK BY OPHTHALMOLOGISTS IN INDIA IN 1929.

By R. E. WRIGHT, C.L.E.,

LIEUTENANT-COLONEL, I.M.S.,

Superintendent, Government Ophthalmic Hospital, Madras.

IN the first week of January 1929, the Sixteenth Indian Science Congress met in Madras. Lieut.-Col. R. E. Wright, the president of the Section of Medical and Veterinary Research, gave his presidential address on "Ophthalmology in relation to research." It is quoted in full in the *Proceedings of the Indian Science Congress* published by the Asiatic Society of Bengal, and in the *Indian Medical Gazette* of May 1929. In addition to briefly setting forth the recent advances in ophthalmology, the speaker drew attention to the very great importance of the eye in the evolution of man, pointing out that in the opinion of distinguished anthropologists the development of the stereoscopic vision is the determining factor in the evolution of the primates, and the great elaboration of man's brain an attribute of bifoveate vision. The ultimate object of research—the advancement of the welfare of man—is thus fundamentally related to ophthalmological science.

Two papers on ophthalmological subjects were presented. Messrs. C. Narayanan and P. Govindarajaswamy of Pondicherry advocated chaulmoogra oil in the treatment of trachoma. (There does not appear to be general agreement in current literature as to the value of this method.)

A paper was presented by Lieut.-Col. R. E. Wright, Dr. K. Koman Nayar, and co-workers entitled "A preliminary note on an epidemic of superficial punctate keratitis" in which it was pointed out that an epidemic of this condition had been prevalent in and about Madras during the latter half of 1928. Some 500 cases had been observed, and an investigation was in progress at the Government Ophthalmic Hospital, Madras. The text of this paper was not published, but an abstract appears in the *Proceedings of the Congress*. A further report presented at the International Congress of Ophthalmology held at Amsterdam is referred to below.

In the *American Journal of Ophthalmology* Saradindu Sanyal contributes an article on "Colon bacillus infection of conjunctiva in adults." The muco-purulent conjunctivitis associated with corneal ulcer without hypopyon has to be diagnosed from other common muco-purulent infections. The original point of ulceration becomes deep and terraced, and a surface ulcer spreads over the cornea. Prognosis is good except for the interference with vision produced by the spreading ulcer. The diagnosis depends on the finding of Gram-negative rods and the cultivation of the *Bacillus coli*. The condition does not appear to be well recognized in adults.

He also records hernia of the vitreous under the conjunctival flap after cataract operation.

In the same journal Lieut.-Col. Wright describes a new type of cataract associated with the formation of minute hard opaque spherules in the lens, and quotes the reports of Dr. W. U. K. Christie of the Geological Survey of India as to their nature.

Elsewhere Col. Wright confirms the value of O'Brien's method of obtaining akinesia in cataract work by blocking the temporo-facial division of the facial nerve where it runs superficial to the neck of the lower jaw, and considers it an improvement on his own method of blocking the main trunk at the stylomastoid foramen.

In the *British Journal of Ophthalmology* Lieut.-Col. A. M. Dick and M. R. Sawhney report a "case of so-called coloboma of the macula." The fundus in the macular region of each eye showed a vertically ovoid white patch less than half the size of the disc. The patch included the fovea on the right side. There was no other congenital defect. The authors conclude that the condition was congenital coloboma of the non-pigmented type, although against this view it was pointed out that the patches were vertically ovoid, and a cholesterine crystal-like appearance suggested old hæmorrhage or inflammation.

In the same journal Lieut.-Col. Wright describes a "Hypopyon ulcer of the cornea due to *Glenospora graphii*." The appearances were those usually described for aspergillus ulcer. The bacteriological report by Col. Acton showed that the fungus belongs to the Aleuriosporineæ of the genus *Glenospora*.

S. K. Mukerjee contributes a valuable article to the *Calcutta Medical Journal* based on a study of 253 cases of glaucoma occurring in subjects of epidemic dropsy during an outbreak in 1926. He hypothecates a toxic condition possibly acting on the ciliary capillaries. Non-operative treatment based on elimination of possible toxic substances was employed. Trephining was used successfully in a number of cases. The paper presents a mass of interesting detail and should be consulted in the original.

To the *Gazette*, Anklesaria contributes an instructive paper on "Detachment of the retina"

in which he records a complete cure in a myopic case. He reviews the main hypotheses which have been advanced to explain different varieties of detachment and then details his interesting case of reattachment.

R. Gubbay reports on the successful treatment of trachoma with chaulmoogra oil (*see above*).

Nanhorya gives an analysis of one hundred cases of cataract extraction at the Raipur Main Hospital by Smith's method with a flap conjunctiva with a fairly high complication rate.

Gnanadikam writes on "Causes of blindness" from the Swedish Mission Hospital, Tirupathur. It is a statistical report from that institution for ten months of the year 1928 and shows the importance of smallpox, keratomalacia, corneal ulcer, glaucoma and corneal scars. (It is difficult to assess the relative importance of the real causative agents from such statistics, inasmuch as one of the great causes of blindness shown, namely the corneal ulcer, is produced by a number of different conditions such as trauma, smallpox, keratomalacia, gonorrhoeal conjunctivitis and so on. For a true estimation of the causes of blindness one must know the ætiological factor, not the resultant damage to the eye.)

Varma publishes a note on the treatment of night blindness by sub-conjunctival injections of bicyanide of mercury or 10 per cent. saline and claims that one injection was enough to cure. The claim seems astonishingly optimistic. The type of night blindness, the numbers treated, and the presence or absence of avitaminosis are not stated.

Jadavji Hansraj publishes a case of abscess of the iris. He points out that abscess of the iris is rare and not described in standard textbooks. (The clinical features quoted are perhaps not so rare, as the appellation abscess given thereto.)

Lieut.-Col. Wright draws attention to the practical value of Webster's operation for entropion of the upper lid.

An important editorial appears in the September number on "Preventable blindness in India" in which it is pointed out that much is being done both by Government institutions, medical missions, and voluntary organizations such as the Blind Relief Association, not only for the relief of blinding diseases but towards the prevention of those conditions which give rise to blindness. The latter is the huge problem to be solved. The essentials in the campaign are education and propaganda and the organizations mentioned might perhaps do more in this way. We are reminded that the blind are innumerable all over India to-day and that preventable blindness is one of India's biggest future public health problems.

The same issue reviews the Report of the Government Ophthalmic Hospital, Madras, for 1928 by Lieut.-Col. R. E. Wright, which can only

be very briefly referred to. The importance of blocking the seventh nerve (*see above*) and the ciliary ganglion, and the use of the bridge flap in cataract work are emphasized. There are a few errors in the review of the cataract section which a reference to the original makes clear. A clinical investigation was conducted on 100 glaucoma cases. Various non-operative measures were tried. The use of the adrenalin pack is mentioned. (An article on the value of this procedure was published in the *British Medical Journal*, Vol. II, 1929, by Lieut.-Col. Wright and Dr. Koman Nayar). The report also treats of lymphoblastoma of the orbit and allied conditions, an article on which was published in the *Lancet* for January 1929. Radium treatment as applied to a variety of orbital growths is described and interesting tables of the blood pressures of hospital patients given. Preventable blindness in the Madras Presidency and the importance of methods of prevention are discussed. Reference is also made to interesting case reports and the investigation of an extensive epidemic of superficial punctate keratitis (*see below*). The reviewer considered that the report should be read in the original by those interested in ophthalmic work.

The Thirteenth International Congress of Ophthalmology held at Amsterdam and the Hague in September 1929 was attended by a large number of ophthalmologists from all over the world and 250 communications were submitted. The subjects chosen for symposia were:

The ætiology and non-operative treatment of glaucoma: the geographical distribution and the international social campaign against trachoma; and the diagnosis of suprasellar tumours.

These were opened by Duke-Elder, Gronholm and Harvey Cushing respectively. It would be impossible in the space available to give an adequate idea of the nature of this great congress and its various activities. Full reports will be forthcoming in due course in the various ophthalmological journals. Committees dealt with such important subjects as:

Standardization of the visual examination of railwaymen, motor drivers, seamen and airmen, perimetry, notation of axis of cylinders, etc.

A directory listing ophthalmologists, ophthalmic journals, ophthalmic societies, hospitals and institutions for the blind was compiled. An International Association for the Prevention of Blindness was inaugurated, an antitrachoma league established, and much other valuable work carried out.

Two papers were presented from India and abstracts of them will appear in the *Transactions* of the Congress, one by Lieut.-Col. Duggan and B. P. Navati on "Two cases of quinine amblyopia with unusual ophthalmoscopic picture." The quinine had produced rapid blindness with œdema of the retina, vessels and discs remaining normal. The vision recovered, but

contraction of the fields remained in each case. The second paper by Lieut.-Col. Wright and co-workers was entitled "Superficial punctate keratitis, a record of an epidemic which appeared in Madras about May 1928 and continued during the year that followed, embodying observations relating to the clinical appearances, bionicroscopy, epidemiology, ætiology and histopathology of the disease on the investigation of over 500 cases." As neither the Congress abstract nor the full text of this extensive work will appear in print till the middle of 1930, it may be well to give the outstanding features of this interesting clinical research. It was pointed out that the disease met with in such an enormous number of cases was the same as that described by Fuchs in 1889, and subsequently mentioned in standard works. Forms were observed which embraced not only the type description but many varieties of keratitis described as independent entities in the literature and intermediate transitional forms. Under epidemic conditions the inclusion of such diverse forms in a common ætiological group was hardly questionable. The affection is apparently closely related to, but clinically distinct from herpes zoster ophthalmicus and herpes febrilis. The investigation undertaken by the Government Ophthalmic Hospital with the co-operation of the King Institute of Preventive Medicine, Guindy, essayed to elucidate the question of ætiology. A bacterial agent was excluded, but the disease was reproduced in the rabbit and man experimentally, using both filtered and unfiltered material. Finally inclusion bodies were demonstrated in the corneal epithelial cells at the site of the lesion. They were more suggestive of Negri bodies or the inclusions of variola than other varieties of cell inclusions. The conclusion seemed justifiable that superficial punctate keratitis with its very varied clinical manifestations was a disease of the herpetic group due to a filter-passing virus and that the occurrence of such distinctive clinical and pathological features is in favour of an independent herpetic syndrome not identical with herpes febrilis or herpes zoster ophthalmicus. To bring information up to date on this subject it may be stated that the epidemic on which this paper was based continued with increasing vigour up to the end of the year under review, over 3,500 cases having been recorded. It became more and more obvious as time went on that the variations in clinical appearances were even greater than originally supposed, the general characters changing markedly during the course of the epidemic. It is comparatively easy to make a diagnosis under epidemic conditions, but the more uncommon clinical types would be almost impossible to recognize when occurring sporadically without some criterion.

Much confusion undoubtedly exists in the literature in connection with this affection which recent experience in Madras will do much to clarify. The affection is apparently an independent virus disease, afebrile, and not

necessarily preceded by a febrile disturbance. It is presumably an air-borne infection, of unknown incubation period (under a week experimentally, shortest period observed under natural conditions one month), of sudden onset, attacking the conjunctiva and cornea, but not the skin. It more commonly involves the left eye, but may invade either eye or both. One attack does not convey immunity. It manifests itself as a rule by a greater or lesser degree of redness, swelling, and discomfort, in this order of prominence, associated with the appearance of minute lesions on these structures consisting of points of infiltration, which show on the conjunctiva as tiny elevations, and on the cornea as grey spots of various sizes. These do not show a tendency to ulcerate although the epithelium may be shed. The corneal appearances are extremely variable and can only be fully appreciated with the corneal microscope. The cornea may actually be spared, more frequently the conjunctiva escapes. Presumably the route of invasion is via the fifth nerve endings. There is always some degree of anterior uveitis, but deeper lesions have not been observed. The disease tends towards complete spontaneous recovery in less than a month in mild cases. In more severe cases round corneal macule may remain, sometimes for a prolonged period. Subsequent interference with vision is rare. The symptoms are commonly much milder than the external appearances would suggest and the bacteriological findings in conjunctival smears within average limits.

POST-GRADUATE COURSES IN EDINBURGH AND VIENNA.

By W. C. SPACKMAN, M.B., B.S. (Lond.), F.R.C.S. (Edin.), M.R.C.S., L.R.C.P.,

MAJOR, I.M.S.,

Professor of Gynaecology, Grant Medical College, and Superintendent, Mottibai and Petit Hospitals, Bombay.

THE following notes, the result of recent visits to Edinburgh and Vienna, may be of interest to readers of the *Indian Medical Gazette* and especially to those who are contemplating going to Europe for post-graduate study.

Edinburgh.—It is best to stay somewhere near the Royal Infirmary. Rooms are easily procurable and are relatively cheap though by no means luxurious. A good room with fires, lighting, attendance and two meals a day costs about 45s. a week. A ticket for attendance at all the routine clinical teaching at the Royal Infirmary must be procured, at a nominal cost. Coaching classes are highly organised and more expensive. The best are those given by junior members of the Royal Infirmary staff and cater especially for the candidates for the F. R. C. S. Ed. examination. In such classes, as in the teaching at the Royal Infirmary, great emphasis is laid on a thorough knowledge of surgical anatomy, and all the latest work in surgical pathology is well taught.

The surgeons who seem especially worth following are Professors P. D. H. Wilkie and John Fraser, whilst Dott is exceedingly good in surgery of the brain and H. Wade in urogenital surgery. They are also exceptionally fine teachers.

Very few men go to Edinburgh for post-graduate work in medicine, but there are good opportunities for theoretical work in gynaecology and for seeing all types of operative procedures in all branches of surgery.

In short, Edinburgh is a very good post-graduate surgical school with special reference to the requirements of the examination candidate.

Vienna.—This is a splendid centre for acquiring a practical knowledge and technique in any branch of practice from the definitely clinical point of view. Liaison with the teachers is established through the American Medical Association, who are most cordial and helpful to strangers, and they run an auxiliary for fixing you up in suitable accommodation. Here as elsewhere it is a good plan to go first to a hotel and not to move until you have found other accommodation that suits you. The cost of rooms varies considerably, but a well-furnished sitting-room with adjoining bedroom in the vicinity of the main group of hospitals may be obtained for about the equivalent of two guineas a week, including a light breakfast. There are innumerable cafes and restaurants where meals of every description may be obtained at very reasonable cost, and if you are in a hurry a most palatable snack may be had at an automatic buffet where you obtain your selected food with a glass of beer or even of so-called Tokay by inserting small change in penny-in-the-slot machines. These buffets appear very clean and well run. There are also many smaller hotels and pensions for those who prefer them.

Whilst in Vienna, opportunity should be taken to visit its charming surroundings and its magnificent buildings and parks. Winter sports had started early in November only 3 or 4 hours away, and in midwinter can be reached for a 2d. tram ticket. Incidentally the trams run everywhere, all tickets cost 2d. and you can transfer through several trams to reach your destination, on the same ticket.

There is a wonderful opera season from September to May, and there are two good golf courses, with lot of tennis and bathing in the summer.

The principal group of hospitals, the Allgemeines Krankenhaus with the neighbouring Kliniks, situated close to the American Medical Association's rooms at Vienna IX, Alserstrasse 9, contains an aggregate of about 3,000 beds and has a large out-patient attendance (ambulatorium). There are also many other associated hospitals in the town with teaching facilities. There appear to be comparatively few Austrian medical students, and post-graduate instruction is almost the sole means of livelihood of the Docents or assistants to the Professors. These assistants are paid about £105 per annum but make a much larger income by teaching. They are usually men of many years of experience and special ability, and they nearly all teach in English, but their mastery of English varies considerably. They work all day long in the hospitals and do but little work outside. Their day begins at 8 or even at 7 (at least one starts at 6) and goes on to 8 or 9 at night. Thus the post-graduate must be ready to work at such hours, though he may find he has a long hiatus without classes in the middle of the day.

The cost of the teaching depends entirely on how many share it. The system is that a vast list of courses is posted up at the A. M. A.'s rooms, lasting according to the subject from 1 hr. (e.g., cisterna puncture), to 20 hrs. (systematic and operative gynaecology) or more. A limited number of men is taken for each course and each course is repeated as required. As an example, a course is given about twice a month on "sterility, Rubin's test and hysterography" from a clinical and practical standpoint, for 4 men, 4 sessions of an hour, i.e., at the same hour daily for 4 days. The cost is 5 American dollars an hour, which the men taking the course divide between them. The finance is all worked out by the A. M. A. and they collect and distribute the money. All courses are reckoned in American dollars but can be paid in Austrian schillings. The standard rate is 5 dollars an hour.

The courses may be either purely didactic, or practical with just the necessary amount of theory as you proceed. Both types are usually very good but in the writer's opinion the great value of working in the Vienna Hospitals is the remarkable opportunity it offers for practical

work. For example, where else can you examine with the cystoscope several pathological bladders in an hour, catheterising all the ureters (if you can) and doing the more usual cystoscopic operations, under the exclusive direction of an expert, and continue daily for so long as you wish, for 5 dollars an hour? In Vienna there are a dozen men whom you can go to, but if you undertake such work it is really better to go and see them privately and arrange a suitable hour.

At the same time, if you take individual tuition it naturally increases the expense, which may easily come £3 or £4 a day for tuition alone.

Here I should like to emphasise a point that I consider very important: do not wait long for the A. M. A. lists to fill if you are at all pressed for time. If the course you want hangs fire go and see the A. M. A. orientation man for that subject about it, or better still the teacher himself. If you arrange personally with a teacher you pay the teacher direct, not the A. M. A. This organisation will not like your doing this, but it is often the only way to get the work you want if you are in a hurry.

Cadaver surgery is easily obtainable in any branch. It costs the usual 5 dollars an hour to the demonstrator with a tip added for the porter at 4 or 5 schillings a body. A schilling is 7d.

One is inclined to be surprised in these clinics at seeing what a hold the manufacturing chemists have over the therapeutic armamentaria of all the teachers from the professors downwards. I have in my notebooks the names of dozens of drugs, mostly of recent introduction, with proprietary names (and often of concealed composition) which are used and recommended officially. In most cases the active principle or approximate formula is given by the maker, but some of the teachers seem quite content to let it remain in their minds under its mystic trade name. For example, a drug was being recommended as a sedative and hypnotic, but the teacher had no idea to what pharmacological class it belonged although its full chemical name was printed on the container and revealed it as a member of the Butane group.

There are of course numerous other centres in Europe where facilities for post-graduate study exist, but they are not so highly organised as at Vienna. In Buda Pest and Prague and elsewhere operations can be bought. You pay a certain amount to your teacher and do the operation under his direction, but you must satisfy him of reasonable preliminary competence and you are not welcomed by his regular assistants. But Buda is so beautiful and so interesting that it at all events should be visited, by steamer in summer, a lovely trip of 14 hours down the Danube; by train or by air in winter. The latter is pleasant and well organised. A party of us hired 4 aeroplanes for this trip.

Part II.

Clinical Notes.—It is thought that a few notes illustrative of current opinion and practice in Vienna may be of interest. It is regretted that they do not cover more than a very limited group of subjects.

Urology.—It is very unusual for any anæsthetic to be used in cystoscopy, and even fulguration treatment may be carried out without anæsthesia provided the terminal is kept in contact with the growth and not allowed to touch the bladder wall.

For pyelography, "umbrenal" is used. This is a strong solution of lithium iodide, about 33 per cent, and is considered much safer than sodium bromide. It appears probable however that the days of pyelograms made with the ureteric catheter are numbered on account of the recent introduction of a very important new group of drugs administered intravenously, just as sodium tetraiodophenol-phthalein (often called STIPP for short) is used for making cholecystograms. One such drug is called Uroselectan and another is Pyelognost. I saw the former used in several cases and was struck by the splendid pyelograms obtained and by the fact that as a rule the patients appeared to stand the drug without any ill effects.

This new method has a number of obvious clinical advantages. It does not depend on the often difficult and occasionally dangerous procedure of passing a ureteric catheter. It is less unpleasant from the patient's point of view. It outlines not merely the pelvis of the kidney, but the secreting tubules and medulla and the ureters of both kidneys at once and continues giving good pictures for 2 or 3 hours.

Drugs of this class are at present being used only experimentally and are not for sale even to hospitals. It is reasonable to suppose however that the method will soon be past the experimental stage.

It is perhaps advisable to emphasise that a very great deal of valuable information in kidney and bladder diseases, to say nothing of treatment, can be obtained by cystoscopy, chromocystoscopy and ureteral catheterisation which the above new method cannot supply. Moreover really good X-ray plants are required for pyelography and even then pyelograms are often very difficult to read. In fact, they must be read only in conjunction with the other methods detailed.

In Vienna many cases of "chronic appendix" in women are treated by drainage of the right kidney with the ureteric catheter. Of this drainage more below.

For outlining the bladder 25 c.c. of Iodipin oil is injected per urethram followed by an equal amount of air.

Chromocystoscopy.—The dye used for testing renal function is 5 c.c. of 0.4 per cent. indigo carmine by intramuscular injection. This should appear simultaneously from each ureter in 5 to 12 minutes. The test is carried out by passing both ureteric catheters, then withdrawing the cystoscope and letting the catheters drip into two test-tubes. The kidney pelvis are thus drained and the patient can be put comfortable while the appearance of the colour is being looked for.

Many cases of pyelitis, especially in pregnancy, are cured by passing a ureteric catheter about 10 to 15 cm. up the ureter, i.e., above the brim of the pelvis where the ureter is subject to the pressure of the pregnant uterus, and leaving it there from 24 to 36 hours, by which means the muscular tone of the ureter and renal pelvis is given a chance of being restored.

Pyelitis that does not yield to internal medicines can usually be rapidly and greatly improved by lavage of the renal pelvis per ureter with weak solutions of silver nitrate, and a clear urine obtained after prolonged pyuria. This of course presupposes a primary bacillary pyelitis and not one secondary to a calculus or growth. Further, no attempt at such local treatment must be made in renal tubercle.

Gynaecology and Obstetrics.—Hystero-graphy is rarely performed except to distinguish congenital malformations of the uterus, e.g., in the diagnosis between ectopic pregnancy and pregnancy in one horn of a bicornute uterus.

It is held that Rubin's test supplies with very little danger nearly as much information as hystero-graphy and that the latter should not be done if Rubin's test shows one or both tubes to be patent. The apparatus used is very simple, an air bellows as for a Junker or even a good 20 c.c. syringe, a mercury manometer and a Rubin cervical cannula fitted with a little clamp adjustable to take the handle of the volsella. No anæsthetic is needed, or at most a little novocaine into the *portio*. Perturbation by the same method is also used when the tubes have been artificially opened, both at the operation and daily for the first four days after, to maintain their patency.

X-RAYS AND RADIUM IN GYNÆCOLOGY.

Cancer cervicis uteri.—The preoperative use of x-rays in cancer cases is not in vogue because (1) it is held that intra-abdominal healing is much delayed, and (2) the inflammatory induration so commonly found associated with the cancer keeps in check the spread of the cancer cells along the lymphatics, although its removal by the radiation certainly facilitates the operation. Radium (in conjunction with x-rays) is only used in inoperable cases and there is a return to its local application as against deep insertion of needles whereby

the bladder or ureter is so frequently injured. Radium is not used where the rectovaginal septum is definitely infiltrated with growth for fear of early development of a recto-vaginal fistula.

Chorion-epithelioma.—X-rays are preferred to operative treatment, this type of cell being of course particularly susceptible to radiation.

Post-operatively, radium is not used. X-rays—the technique of Warnekros of Berlin—is favoured in preference to the Erlangen. The finest and most modern apparatus is needed so that the x-ray tube may be far enough from the skin to eliminate nearly all but the most penetrating rays and yet require not too tedious an exposure. A full carcinoma dose is given, as soon as the patient has regained control of the bladder, i.e., usually 3 or 4 weeks after operation, and this may be repeated at intervals of 3 months.

Other Uses. There is a conspicuous vogue at present for irradiation of the hypophysis, *per fossas temporales* for the following conditions in which it is said to give excellent results. There is no danger of injury to the brain, as the brain cells and nerve fibres are not liable to growth by cell division after infancy, and are therefore extremely resistant to radiation.

1. Severe primary dysmenorrhœa and menorrhagia, or for amenorrhœa, in young girls where ovarian stimulation is desired. It is specially pointed out that although good effects can be obtained by stimulation of the ovaries by rays and the patients may resume normal menstruation later, their children are small and unhealthy and show a liability to tuberculosis. In animals where the same ovarian irradiation is given, the third generation are sterile. It seems that ovarian radiation whilst destroying the full grown ova permanently damages the immature ones so that although they ultimately may be fertilised they are weak or defective from the start. In a series of 70 who after radiation later became pregnant, the miscarriage rate was doubled and two children were grossly deformed. Hence pituitary radiation, which gives as good results clinically, is preferred.

2. For climacteric depressions where no definite psychosis is present, and for relieving the symptoms of the post-operative menopause if these are severe.

3. In pruritus of pregnancy.

Hyperthyroid patients are refractory to the above treatment.

Radiation of the Spleen: 1½rd erythema dose for early control of menstrual hæmorrhages, to be repeated each period. Also for subinvolution with red lochia. And for hæmophylies before operation.

Radiation of the liver might be tried for the anæmia of pregnancy, although this appears to yield to a few small blood transfusions by the indirect method.

Irradiation of the abdomen gives excellent results in tuberculous peritonitis with or without laparotomy. Dosage 1½th ovarian dose daily for 10 days. This is regarded as the best treatment for tuberculous peritonitis.

Fibroids.—X-rays are regarded as a very suitable treatment for fibroids, but only for those which produce no other symptom except severe and prolonged menstrual bleeding. In all other cases operative treatment is preferred.

It is perhaps advisable to add that the x-rays referred to are the hard rays, not those used for diagnostic work.

Kielland Forceps.—Kielland forceps are almost exclusively used in the obstetric clinics, and their application is very well taught by the aid of a phantom pelvis with rubber fittings and a preserved still-born foetus. The course of instruction and practical work given to post-graduates in their use lasts for 3 sessions of an hour each. It is held that these forceps can be applied in all cases where forceps are of use and in many high cases where no other forceps could be applied. Certain points however must be observed in using them in high (unengaged) cases to avoid the accidents that have brought them under suspicion in some quarters.

Among these are:

1. The pelvic curve must be pointed towards the presenting part, e.g., occiput. The *anterior* blade is inserted first, but with its cephalic concavity directed *forwards* until it has completely passed the symphysis. It is then allowed to rotate away from the presenting index for 180° to engage the head anteriorly. In introducing it, with the patient in the dorsal position, the handle must be depressed well down towards the coccyx as soon as the other end is past the anterior lip of the cervix. As regards the rotation, there is a dot on the side of each blade handle to indicate which direction this rotation should go, but if the blade will not rotate easily in that direction it is probable that the diagnosis as to side of presentation is wrong and in that case the blade will be found to rotate readily the other way.

2. The anterior blade having been applied, the posterior follows the sacral curve and is easily applied and locked. This lock is really a slot and allows one blade to be at a slightly different level to the other by a sliding action.

3. When the head is brought past the brim, an indication must be looked for that it has reached the level at which it will rotate into the antero-posterior diameter. Rotation is then performed with the forceps, but there must be no pulling downwards during this, but on the contrary the head must be pushed back a little to relax the tension on the vaginal wall. The severe tears in the upper part of the vagina, usually circular and sometimes complete, reported after the use of these forceps, are held to be solely due to a disregard of this most important rule.

4. The last step in the delivery of the head is not a pull but a leverage upwards of the handle over the symphysis.

5. In dealing with the after-coming head, the forceps can be applied either in front of or behind the body, as is most easily done.

6. Catheterisation of the bladder is deprecated by Kielland because so long as the bladder is not empty it will remain above the pelvic brim and will not be nipped between forceps and symphysis.

The use of forceps in labour under hospital conditions is more frequent. It is held that the damage to the muscular and fascial components of the pelvic floor so commonly followed by prolapse and cystocele is caused by the *prolonged* overstretching it has been our custom to encourage and applaud. As a corollary, episiotomy is a common procedure.

It is worth noting that the great majority of foreign obstetricians visiting Vienna go away with a pair of Kielland forceps in their baggage!

Placenta praevia: Caesarean section is reserved for primiparae with central or marginal placenta, bleeding through undilated os. Other cases are treated by rupture of the membranes, and the application of Willett's scalp forceps is replacing the Braxton Hicks method of podalic version.

Eclampsia: Conservative treatment with sedative drugs holds the field.

Thymophysin: this drug, which is a mixture of extracts of pituitary and thymus, is in use in all the teaching obstetric clinics in Vienna and very widely in Germany; it is given in place of pituitrin in labour. It produces regular contractions of the uterus, never tonic or spasmodic and is used in all stages of labour freely. It was recommended by Prof. Werner in his systematic lectures to post-graduates last autumn and is highly spoken of by the teaching assistants.

MISCELLANEOUS.

Blood Transfusion.—Both direct (whole blood) and indirect (citrate) methods are used, direct to replace blood lost by haemorrhage and to combat infections, indirect to stimulate blood formation. The former is given once as a big transfusion, the latter in a number of smaller amounts once a day or as required.

Transfusion for haemorrhage is much less common than formerly: cases with normal pulse rate and blood pressure recover with hot drinks, etc.; cases with normal

pulse rate and low pressure or with rapid pulse but normal pressure by intravenous saline ("normosal" is used) and only cases with rapid pulse and low pressure are given blood. In septicemia, immuno-transfusion is advocated but without much enthusiasm, and the usual methods of protein therapy and administration of colloidal metals and of iodine are freely used under their proper indications.

Varicose Veins.—The method used is to immobilise the blood in the vein by two tourniquets about an inch apart, and to inject into the portion thus isolated 60 per cent. laevulose to distention. This appears effective under the technique taught and is certainly far less irritating to the tissues than salt, salicylate or rather, sclerosing fluids when a little escapes under the skin.

Anaesthetics.—Every variety of anaesthesia is in use. Open ether is perhaps the favourite, but a good anaesthetist seems hardly more common in Vienna than in India. *Spinal* must not be used for small operations as it produces headaches much more frequently in these than in bigger procedures. Duttner says his needle, which is a double one, the inner one being of very fine calibre, does not produce headaches.

Acetamin is very well thought of, but a little general anaesthetic is always wanted in addition and the half-hour or so needed for it to take effect is a nuisance in hospital practice. However it is likely to be much used in future, especially in private practice and for nervous patients.

Finnsterer follows his coeliac technique, which gives splendid relaxation and almost no shock.

Sacral and parasacral anaesthesia are both used, and so of course is infiltration and nerve blocking in all their varieties. A good description of these can be found in Ogilvie's *Recent Advances in Surgery*.

Percaine is spoken of as by far the best local anaesthetic both for mucous membranes and for infiltration. In the latter case, it is used in 0.05 per cent. solution, can be boiled, keeps well, and before use 1 per cent. of 1 in 1,000 adrenalin to be added. It is of recent introduction and of Swiss origin. Is it possible the ideal local anaesthetic has at last appeared?

It seems remarkable that such excellent surgical results are obtained where both the anaesthetic and nursing arrangements appear somewhat primitive. As regards the nursing, this is largely done by *religieuses* who appear to have neither the numerical strength nor the professional prestige to which we are accustomed. They are certainly very hard-worked. The patients are long-suffering and submissive, and are remarkably good to each other in the way of helping all they can in the wards. Even many who appear very ill may be seen doing nursing and menial duties. The wards are more crowded than is our custom. They are very clean, of a bleak soap and water cleanliness rather than of polish and glazed tiles.

Medical News.

A HOT WEATHER IDYLL.

As our military readers know, the Great War was associated with an almost universal prevalence of that distressing malady *Teniasis rubra* (infection with the red-tape worm). We have received from a correspondent the following fragment, dug out of an old record. Unfortunately it ends abruptly, and one does not know whether the "Hog, hedge, I" ultimately secured any diet or none. The correspondence is vouched for as genuine.

Scene.—Mesopotamia in July. Maximum daily shade temperature about 125°F.

Correspondence between the O/C. Ration Department R.A.S.C. and the O/C. Central Laboratory.

I. From O/C. Rations to O/C. Laboratory. Memo. "Your indent of 2nd instant states that you require grain and fodder for 147 animals. Please

classify these animals and quote your authority for including them on the ration list."

II. From O/C. Laboratory to O/C. Rations. Memo.

"The animals referred to are those required for laboratory diagnosis. No special sanction has been obtained, but they are referred to in *Field Medical Annual*, Vol. V, Footnote to para 178.

'Equipment. Accessory, laboratories, for the use of.'

III. From O/C. Rations to O/C. Laboratory. Memo.

"In reference to your memo of 9th instant, it is essential that the animals should be classified under the usual headings in order that they may be admitted to the ration strength of this Corps. Please return them under their respective headings as under, which are the animals sanctioned on the strength.

Horses over fifteen hands.

Horses under fifteen hands.

Horses, general service.

Ponies, grass cuts.

Ponies.

Bullocks, draught.

Bullocks, milch.

Asses, country.

Any alterations in the ration strength of the animals under your command should be reported to me by wire immediately on said increase or decrease."

IV. From O/C. Laboratory to O/C. Rations. Memo.

"The animals under discussion belong to the following classes and you are requested kindly to lay down for my guidance the daily ration of each in (a) grain, and (b) green fodder.

Hares, Belgian	62
Pigs, guinea	84.
Hog, hedge	1."

V. From O/C. Rations to O/C. Laboratory. Memo.

"In reference to yours of 14th instant, I have to inform you that in consultation with the Divisional Officer Commanding R.A.S.C. and the Director-General Local Resources I have fixed the following scale for the rations for said animals and this should be adhered to by all animals under your command.

Hares, Belgian, per head per diem	grain 1½ ounces.
			lucerne 2 "

Pigs, guinea, per head per diem	grain 1 ounce.
			lucerne 1½ ounces.

Hog, hedge, may be classed for this purpose as a Pig, guinea.

Requirements should be submitted daily before 8 a.m., and the animals should be returned in the following classes:—

(a) Sucklings; (b) partially weaned; (c) weaned; (d) on full diet. The amounts of food-stuffs sanctioned for each of above classes should be calculated as 1/17th, 1/11th, 1/6th and 1/1th respectively of amounts sanctioned above."

VI. Telegram from O/C. Laboratory to O/C. Rations.

"Begins. Your memo dated 12th instant, ration strength of animals referred to increased from 147 to 194 in last three days. Please correct accordingly. Ends ack ack ack."

VII. Memo from O/C. Laboratory to O/C. Rations.

"Reference your memo No....., your order re. marginally quoted animal being classed as 'Pig, guinea,' is inadmissible as this animal Hog, hedge refuses to consume rations provided and requires insect food. Please arrange."

VIII. From O/C. Rations to O/C. Laboratory Memo.

"Regret to inform you that insects are not an issue in this department. Please try Director-General of

Agriculture, quoting his *Field Manual*, Vol. XXVII, para 2794(62 (a), ii.

'Eggs. Ant's, canaries, for the use of.'

If not in stock try the Medical Store Department which has an issue of insects (vide *D.M.S.M. Standing Orders*, 1916, para 272 (d) 3) under the sub-heading of 'leeches, medicinal, medical officers, for the use of.'

THE INTERNATIONAL SOCIETY OF MICROBIOLOGY.

At the International Conference on Rabies, held in Paris in April 1927, it was decided at a meeting presided over by Professor Madsen of Copenhagen to found an International Society of Microbiology. The object of the Society is not only to stimulate scientific advance by creating a more active co-operation between the workers in different countries, but also to foster the idea that Science should unite the nations in an ideal of durable peace and solidarity of investigation. It was decided that the subjects dealt with by the Society should not be limited to bacteriology, but should include also the other sciences included under the comprehensive term "microbiology,"—such as parasitology in its widest aspects; medical, veterinary and agricultural microbiology; botany; mycology, etc.

The Society will hold international congresses from time to time in different countries. The First Congress will be held in Paris from the 20th to the 25th July, 1930, under the presidency of Professor Jules Bordet of Brussels. The programme for this Congress is an extremely interesting one. Of the three sections of the Congress, the first deals with medical and veterinary microbiology; Professor Bordet, Dr. d'Herelle, and Dr. Ledingham will deal with the questions of microbial variation; Dr. Flexner and Dr. Levaditi amongst others with neurotropic and filterable viruses; Dr. Kitashima with the pathogenesis of cholera; and Dr. Pfeiffer with influenza. The second section will be devoted to serology and immunity; and here Dr. Sachs will deal with the rôle of lipoids in immunity. The third section deals with parasitology and botany; here Dr. Buchanan and Professor Uhlenhuth will deal with spirochaetes of water origin, Dr. Nicolle with blood inhabiting spirochaetes, and Dr. M. Mayer with Bartonella and similar infections in splenectomized rodents. Numerous special conferences and demonstrations have been arranged; these include an address by Professor Calmette on antituberculous vaccination, demonstrations by Dr. Borren on tissue cultures, one by Professor Inada on spirochaetosis ieterohemorrhagica, and one by Col. Russell, I.M.S. (retd.), on malaria. A special commission at the Congress will also concern itself with the difficult question of nomenclature in microbiology.

National committees of the International Microbiological Society have already been formed in twenty-three countries, and the importance of having such a committee in India is very obvious.

The fee for attending the Congress is 100 francs, and the Treasurer is M. Georges Masson, Editeur, 120 Boulevard Saint-Germain, Paris (VI). Messrs. Thomas Cook and Sons are arranging for accommodation and railway travel.

ALL-INDIA OPHTHALMOLOGICAL SOCIETY.

THE First Annual Meeting of this Society will be held in Bombay on the 17th, 18th, and 19th of April 1930. Those who are desirous of joining the Society and of reading papers at the First Annual Meeting are requested to communicate immediately with Dr. G. Zachariah, Hon. Joint Secretary, Flitcham, Marshall's Road, Egmore, Madras. The annual subscription to the Society is Rs. 15. The proceedings of the First Annual Meeting will be published in volume form as soon after the meeting as possible, and sent to all members."

Current Topics.

Observations on the Treatment of Pleuritic Effusions.

By Sir THOMAS HORDER, Bt., K.C.V.O., M.D., F.R.C.P.
(Abstracted from *The British Med. Journ.*, October, 5th, 1929, No. 3587, p. 605.)

IN the first place, it is necessary to stress the fact that the successful handling of a case of pleuritic effusion does really rest upon principles, more or less clearly definable, and that the appropriate treatment of the effusion depends upon a consideration of several factors:

1. The cause of the infection.
2. The nature of the effusion.
3. Its size.
4. The stage in the disease process at which the patient has arrived.
5. The associated condition of the lung.
6. The degree of illness of the patient.
7. The contribution made by the effusion, as such, to the illness.

The time-honoured division of effusions into serous, or sero-fibrinous, and purulent is justified both on clinical and on bacteriological grounds, and brings into close association the first and second of the above-named factors:

1. *Sero-fibrinous Effusions*.—Tuberculous; rheumatic; influenzal; lymphadenomatous; some other infections; neoplastic.

2. *Purulent Infections (including Empyema)*.—Pneumococcal; streptococcal; staphylococcal; influenzal; mixed infections; gonococcal; coliform; streptothrix.

The stage at which the disease process has arrived when effusion is diagnosed is a fact of great importance in the decision whether to remove the fluid, and also by what method to remove it. To remove all effusions "at sight" is, undoubtedly, bad practice, and this statement applies alike to purulent as to serous effusions. Care must be taken, however, not to confuse treatment with diagnosis. It is assumed that no effort is spared to make the diagnosis as early as possible; it is also assumed that no one is ashamed of a negative pleural puncture; better a negative puncture too early than a positive puncture too late.

The associated condition of the lung should be assessed with as much care as possible. Active and acute inflammatory changes in this organ contra-indicate removal of pleuritic effusion, *ceteris paribus*, and this is true whatever the nature of the infection, because the presence of the fluid is undoubtedly of conservative value in keeping the lung at rest.

But the accumulation of fluid adds toxic and mechanical factors to the patient's illness, and these must be taken into account in determining treatment of the effusion. The question often arises; to what degree is the patient handicapped by the presence of the fluid, and to what degree is he ill by virtue of his general, or his pulmonary, infection? The proper answer to this question can only be given after the exercise of judgment based upon experience.

Lastly, it is necessary to carry in mind how ill the patient is, though this has more bearing upon the manner by which the effusion is removed, and the rate at which it is removed, than upon the question whether or not it be dealt with.

1. Serous Effusions.

The great majority of these are tuberculous in origin. Their treatment follows traditional lines. If they are very large effusions they are tapped as soon as they are diagnosed. If they are associated with respiratory or cardiac distress, and this seems refractory to the effusion

rather than to other factors, again they are tapped as soon as diagnosed, and irrespective of their size. Thirdly, if they show no signs of (further) absorption after fourteen days or so from the date of their discovery, they are tapped. Too early an interference with serous effusions is meddlesome. There is a definite evolution in the exudative process consequent upon the disease, so that the fluid tends to collect again if removed before its high tide is reached. But a more important reason against premature removal of the fluid is that by such interference the associated collapse of the lung is interfered with, and its expansion encouraged. Should the lung itself be the seat of active tuberculous disease such expansion tends to increased activity, and if it be not itself involved its partial collapse protects it from infection from the pleura. Several days of observation of the patient are sometimes necessary in order to decide if the lung is, or is not, involved, and in cases of doubt it is better to assume that it may be. Too late an interference with a serous effusion, on the other hand, is prone to leave the lung permanently collapsed, with consequent deformity of the chest and scoliosis.

If there is evidence that the lung is diseased, and in proportion as this evidence is definite, even greater care must be exercised against too hasty removal of the liquid effusion. Our experience of the good result of collapse therapy in the treatment of some cases of pulmonary tuberculosis has an obvious bearing upon this matter. The replacement of the effusion by oxygen may be considered, and this is sometimes done with excellent results. The production of active symptoms of lung disease is not infrequently witnessed as the result of the rapid expansion which follows removal of a serous effusion when a latent focus of tubercle is present. Less often, but more serious still, a pneumothorax, with all its lamentable consequences as a complication of pulmonary tuberculosis, ensues from the same error in practice.

Whilst this policy of forbearance is in operation the doctor is not idle. The patient is, from the first, regarded as suffering from tuberculosis, and the general measures that follow upon this view are put into action. The arm on the affected side is immobilized; perhaps that side of the chest is strapped, unless it be decided to paint the skin with equal parts of the tincture and the liniment of iodine, or to apply some other form of counter-irritation. Iodides are given internally, and calcium is thought by some to be of service.

Expectant treatment of serous effusions, followed by simple removal of the liquid at a well-chosen time in those cases in which it does not undergo spontaneous absorption, is so successful that to complicate it by or to substitute for it, other methods seems a matter of supererogation.

How to remove pleuritic effusion, when the conditions indicate this need not be dealt with here in detail. With most practitioners the Potain type of aspirator is deservedly more popular than the method of siphonage. With the latter there is often uncertainty whether cessation in the flow is due to absence of more fluid or to blocking of the tube by clot; whereas with aspiration, provided the operation be not hurried, and the patient be made quite comfortable both in mind and in body, the risk of too rapid expansion of the lung, as shown by cough, hæmoptysis, or "albuminous expectoration," is negligible. Care should be taken to see that the local anaesthesia is really effective, and there is much to say for the preliminary use of a sharp scalpel, wherewith to nick the skin, before inserting the needle attached to the aspirator. Trocars with cannulas are to be avoided, and the ritual of a major operation, which is sometimes witnessed, is quite uncalled for.

How much liquid to remove depends much upon the individual case. It is very striking sometimes to see fairly rapid absorption started by the removal of quite a small amount. On the other hand, in large effusions, there is nothing to be gained by ceasing the aspiration so long as the liquid flows easily and the patient remains comfortable.

Drugs injected into the pleura after removal of the liquid, at least on the first occasion of its removal, are of dubious value. It is a question whether they do more than satisfy an inherent weakness in human nature to complicate a simple procedure.

The after-care of the patient follows the lines indicated by the knowledge that he is almost certainly tuberculous. Therefore his convalescence must on no account be hurried. Nor must so-called "respiratory gymnastic" be brought into the scheme of treatment too soon—certainly not before the pyrexia has completely ceased, redness and friction has disappeared, and any other evidence of active inflammation has subsided. Otherwise there is, once more, the danger of "lighting up" a latent lung focus or of a relapse in the acute pleurisy. A return to ordinary life must not be considered under three months from the time of cessation of symptoms, and it may be necessary to extend this period if the season of the year is unfavourable or the case has been tedious. Even then there should be rules for daily observance, as for an early case of pulmonary tuberculosis.

Rheumatic effusions are almost invariably accompanied by other expressions of rheumatic inflammation, especially by some form of carditis, and their treatment becomes part of the therapy of acute rheumatism. Aspiration is rarely necessary.

Serous effusions in influenza are either associated with active lung disease (pneumonia), when their treatment is determined by this fact and by the degree of illness of the patient; or they appear later as residual collections of fluid when the main illness has subsided, when the question should be carefully considered whether or not the effusion is not really tuberculous. These facts determine their treatment.

In lymphadenoma and in cancer there are no special rules of guidance: the individual case must determine treatment.

2. Purulent Effusions and Empyema.

In the main the principles governing the treatment of serous effusions operate here also. But the time factor is of greater urgency, since the old-established surgical maxim to "evacuate pus as soon as it is discovered" should not be departed from in this or in any other condition. The points under consideration, therefore, are concerned more with methods of drainage than with the time of drainage. And these methods have less uniformity in opinion and practice than is the case with serous effusions, because the conditions of satisfactory drainage of a pleural abscess are obtained with less constancy.

The various methods of drainage and subsequent treatment will now be passed in review.

Treatment by Aspiration, Repeated as Indicated.—When purulent effusion occurs during the active stage of any disease, and especially when it occurs during the active stage of pneumonia, aspiration is the method of election. Both incision and resection should be postponed, but especially resection. In not a few cases one or two aspirations suffice, and major procedures are found to be unnecessary. Not only is this so in pneumococcal cases, it is sometimes the case in septicaemia with focal pleuro-pulmonary lesions of a suppurative nature, especially when the infection is streptococcal. In influenza cases, again, this procedure should always be given a trial before it is decided to incise the chest or to resect a rib. In staphylococcal pyæmia, on the other hand, although aspiration very occasionally succeeds, and should therefore be tried, drainage by the open method will probably be required sooner or later. Speaking generally, the more ill the patient, and the more certain the evidence of existing pneumonia, the more should the practitioner favour aspiration as against the open method. Too much care cannot be given to this consideration; is the patient ill chiefly as the result of his general infection (with or without pneumonia), or is he ill chiefly as the result of the empyema? Upon the answer to this question depends the decision to aspirate, and perhaps to repeat the aspiration, or to incise with

rib resection. The course of the disease must be carefully watched if we are to arrive at the correct answer. The character of the pus is of less importance as a guide to the method to be adopted than are the above considerations. It is assumed that needles of adequate bore are used, and also of adequate length. It is sometimes difficult to persuade instrument makers that there is use for a needle which is bigger and longer than a hypodermic needle and yet smaller than a trocar.

Treatment by Simple Incision and Drainage.—This intermediate method is probably less often indicated, and less often successful, than aspiration on the one hand and resection on the other. But, again, in very ill patients this method may be resorted to with advantage, and especially when the exudate is very thick, and where there are coagula and sloughing pyogenic membrane, as in some pneumococcal cases.

Treatment by Incision (with or without Rib Resection), Irrigation, and Closure of the Wound.—This method has had a vogue of late. It is probably only applicable to pneumococcal cases, and, despite some success, it too often transpires that recourse must be had later to the older, and more tedious, methods. Its pursuit appears to be an example of the hope that technique can, some day, triumph over experience.

Treatment by Incision, Rib Resection, and Drainage.—This is the old-fashioned method, and still remains the method of election in the majority of cases. Matters of purely surgical technique will not be entered into here. But the level of approach, so as to effect the best drainage, the choice of anæsthetic, and the extent to which digital exploration is undertaken are all of them matters which pay for careful thought. Digital exploration is probably of service in most cases: it enables the observer to glean helpful information in respect of the state of the lung, admits of the breaking down of recently formed adhesions, and facilitates the expulsion of sloughs and coagula. But forbearance should be exercised in all this: "Be bold, be bold.... be not too bold." Modifications in the system of drainage in this, the open method of treatment, deserve further consideration and trial. The desiderata are adequate evacuation of the pus, the avoidance of more than local and temporary pneumothorax, and the least disturbance of the (presumed) diseased lung. The use of a tube which is carefully adapted to the chest wall, and which delivers into an air-tight bottle, is worth more extensive trial. Unfortunately in children, who are the very patients in whom the above-mentioned desiderata are of special importance, apparatus of a complicated pattern are difficult to keep in place.

The question of irrigation of the empyema cavity is one which recurs in the minds and practice of successive generations of practitioners. Whilst admitting that the calamity termed "pleural shock" is a rare event—though probably less rare in pleural lavage than in pleural puncture—it is very doubtful if irrigation as a routine procedure is justified by results. A large number of substances have been used at different times. Dakin's solution (5 per cent. neutral sodium hypochlorite) is supposed to have virtue as a decorticator and solvent as well as a germicide. Aniline dyes, such as methylene blue and gentian violet, have been used a good deal of late. Iodoform emulsion and iodized oil have their advocates. Two things seem clear: irrigation at the time of the operation is always of questionable value, and irrigation at any time, either then or subsequently is to be avoided if there be any suspicion of pulmonary abscess in addition to the empyema.

The importance of treating the patient must never be lost sight of. Indeed, the after-care of the patient should receive special attention. Abundant aërotherapy should be adopted, and, whenever possible, the patient should be in the open air for long periods of the twenty-four hours. The diet should be simple. Sunlight and ultra-violet rays are often helpful. The use of vaccines, though not so popular as they were a decade or two ago, should be considered, and general tonic measures are not to be omitted. In this way is combated any residual infection that may exist, and expansion of the lung is

encouraged. Respiratory gymnastics—deep breathing—may well be employed, and less caution is necessary here than in serous effusions, lest such helps be sought too early.

The problem of the residual sinuses is often a difficult one. The help of x-rays and lipiodol injections is notorious. The indications for treatment when the case has arrived at this point depend upon the application of two principles; that a septic focus in the chest, however small, constitutes a general as well as a local danger; and that there are only two ways in which such a focus can be effectively dealt with—either the lung must be allowed to expand until it reaches the chest wall, or the chest wall must be allowed to fall in until it comes in contact with the lung. Which of these two modes of securing permanent healing is chosen, or whether both are chosen, depends upon the particular case. In the first instance digital exploration with efforts at decortication is the method of election; in the latter, the resection of portions of more ribs. Meantime the methods by which the patient's general tone is re-established must not be relaxed. In such difficulties patience, vigilance and the pursuit of the principles stated usually achieve the end desired.

Recent Advances in the Treatment of Gonorrhœa.

By Major CHARLES WHITE, O.B.E.,
and

Major H. G. WINTER, M.C.,

(Abstract from the *Journal of the Royal Army Medical Corps*, Vol. LIII, October, 1929, p. 251.)

THESE writers, for various reasons which they give in detail, prepare a special vaccine in the following manner:—

Large, $6 \times \frac{3}{4}$ inch, tubes of the nucleo-protein medium are inoculated with gonococcal culture and are incubated for twenty-four hours. In order to ensure uniform growth, the same sized tubes, sloped to the same angle, and a standard inoculating loop are used. After twenty-four hours, each tube is washed off with 1.5 cubic centimetres of 2 per cent. saline carbolized with 0.5 per cent. phenol—a separate pipette is used for the addition of the saline and for removal of the emulsion from the tubes, thus ensuring that the stock carbolized saline is not contaminated with gonococcal bodies which might autolyse on standing and release their endotoxin.

The emulsion is put up in vaccine bottles in quantities of twenty-five cubic centimetres. Periodical counts show the average content to be 7,000 106 per cubic centimetres. These bottles are put, with the least possible delay, in a high speed centrifuge giving 9,000 revolutions a minute and are "swung" for about four minutes. After centrifugalization it will be noted that the contents have separated into three layers, a lower greyish layer consisting of the bodies of the gonococci, a middle cream-coloured layer of the α -nucleo-protein element of the polar bodies and a clear supernatant fluid which is a saturated solution of the B -nucleo-histone in a two per cent. carbolized saline. This clear fluid is pipetted off and put in vaccine bottles ready for use. It is not heated. The solid portions might be removed by sedimentation, but high-speed centrifugalization is resorted to because it has been found that the shorter the period the diluting fluid is left in contact with the organism, the less likely to autolysis to take place. Vaccine prepared in this manner will keep well for considerable periods and under varying conditions of temperature, still retaining its antigenic power. The dosage is two cubic centimetres and the optimum interval between doses is six days.

The method of administration is of some interest. We believe that body immunity depends largely on the stimulation of the lymphatic system and that, if a vaccine be given subcutaneously, intramuscularly or intravenously, a large proportion will be excreted before it has been able to exert its antigenic power. Moreover there is a definite danger of thrombosis when saturated solutions of nucleo-proteins are introduced into the blood-stream direct.

For these reasons the vaccines are given intradermally. A dose of two cubic centimetres is, however, too big to administer by this route in one site, it is, therefore, distributed over seven areas as follows: inner and outer wall of the axilla on each side, inner side of both thighs and into the skin at the base of the penis. Provided a fine, sharp needle is used no difficulty is experienced and very little pain felt. The results of the vaccine are a slight local reaction and enlargement of lymphatic glands.

The authors summarize their method of treatment as follows:—

On admission to hospital a smear is taken and if positive the following procedure is carried out:—

(1) Half an ounce alkaline sodium phosphate is given four times a day.

(2) Two posterior irrigations a day are given with 1|20000 pot. permang.

(3) Two cubic centimetres polar body vaccine are injected intradermally in seven places. This is repeated every seventh day for as long as required.

(4) Daily smears are examined and the approximate number of pus and endothelial cells and gonococci are estimated (the numbers are recorded as approximately the number per field, i.e., "G. C. 2|1, P. 4|1, E. P. 1|10").

(5) A rough estimate of the urinary pH is made daily.

(6) The patient is kept "up" on ordinary diet with the addition of vegetable soup twice daily and four pints of barley water (made without lemons).

(7) Two and three times weekly the patients are assembled in the treatment room and their urine examined by the two-glass method. It has been found that, in view of the large amount of phosphate present, glacial acetic acid is frequently required to clear it. It is not suggested that the two-glass method is infallible but, if one method is adhered to, after some experience a good deal of information can be obtained.

(8) Immediately the discharge begins to lessen, irrigations are cut down to one a day and later discontinued. Patients are put on light fatigues at the earliest possible moment.

(9) When a patient has been "dry" for seven consecutive days on no treatment and no light fatigues, he is examined with the urethroscope or straight sound and by prostatic massage. If no evidence of disease is discovered he is discharged from hospital to duty but is kept under observation for six weeks to two months, reporting at first weekly, later fortnightly.

(10) If, during the course of treatment, complications, such as acute posterior urethritis, develop, the patient is put to bed on a low diet with the appropriate treatment. Irrigations are stopped but the vaccine is continued. In fact the treatment of complications is the same as heretofore with the addition of vaccines and sodium phosphate.

Chronic Appendicitis as a Cause of Indigestion.

By M. O. BURKE, M.D.

(Abstract from *Southern Medicine and Surgery*, Vol. 91, No. 6, June 1929, p. 391.)

THERE is a doubt in the minds of many physicians as to the existence of chronic appendicitis; they have some strong evidence in their favour.

Drs. Carnett and Boles, of Philadelphia, presented a paper at the A. M. A. meeting in Minneapolis (1928) entitled: "Fallacies Concerning Chronic Appendicitis." They make this statement: "A clinical diagnosis of chronic appendicitis implies that the patient has a localized disease confined to the appendix, that appendicectomy is indicated, and that the operation will provide a cure. We believe that chronic appendicitis is not a disease limited to the appendix."

Taking these statements literally we cannot confute them. Some claim that operation for chronic appendicitis does not relieve the digestive symptoms. We know that many cases, both acute and chronic, have had

appendicectomies without benefit; some have been made worse. We also know that many patients have died because they did not have an operation soon enough. It is evident that many appendices have been accussed, convicted and executed that were entirely innocent. We are probably prone to convict the appendix when we can't find some other definite cause of the trouble. Discomfort and tenderness in the lower right quadrant does not always indicate appendicitis, nor does tenderness and pain over the same area necessarily mean intercostal neuralgia, as described by Drs. Carnett and Boles.

Is it possible that all of the textbooks are wrong in describing chronic appendicitis? Are the experiences of such physicians as Aaron, Einhorn, Friedenwald, Rehfuß, Smithies and the world-famed Osler worth nothing? Shall we discard the reports of our best radiologists and count as fallacies the experiences of our leading surgeons?

At the twenty-sixth annual meeting of the American Radiological Society, Dr. A. L. Gray reported a series of cases of chronic appendicitis as a cause of acidosis in children, diagnosed as chronic appendicitis, operated on and cured. Deaver and Rodwin report 500 cases of chronic appendicitis with operation: 83.1 per cent. entirely relieved, 9.7 per cent. partially relieved.

Believing that chronic appendicitis is a cause of indigestion has led me to write this paper. Trouble manifested by the stomach is more often extragastric than intragastric.

The following are replies from some of our outstanding gastro-enterologists as to the percentage of cases of indigestion caused by chronic appendicitis: Aaron 10 per cent., Einhorn 2.5 per cent., Friedenwald 10 per cent., Smithies 7 per cent.

In going over my own case histories I find about 10 per cent. of cases of indigestion diagnosed as due to chronic appendicitis; 50 per cent. of these were diagnosed, operated and cured; 50 per cent. diagnosed, not operated, benefited by treatment, but not cured.

CLASSIFICATION.

Royster's classification of chronic appendicitis:

1. Catarrhal.
2. Interstitial.
3. Obliterating.

The types of chronic appendicitis that cause indigestion may be classified as:—

1. Recurrent mild appendicitis.
2. Partial occlusion of any portion of the appendicular canal.
3. Appendices with adhesions.

In some instances of appendicular adhesions the appendix was not the offending party; it was caught in bad company. The appendix may be attached to any of the inhabitants of the abdominal cavity. I have seen it attached to the stomach, producing symptoms of a gastric ulcer and have seen it imbedded in a mass of omentum held fast in the femoral ring. We can readily conceive of trouble when the appendix, an organ two to five inches long, has one end fastened to the cæcum and the other end tied to something several feet longer than itself. Natural peristalsis of the intestines would cause tension on the appendix and extensive peristalsis would cause greater tension; thus producing irritation in the appendix and in the organ to which it is attached.

A narrowing of the lumen of the appendicular canal may permit the entrance of material from the cæcum but may retard or obstruct its exit; as a consequence, decomposition, fermentation and formation of toxins take place, causing irritation, possibly ulceration and absorption of poisons.

Recurrent appendicitis may be of the catarrhal, interstitial or adhesive type, or it may combine all three types. The attacks may be frequent or far apart. The symptoms may be irritative or mildly toxic. The gastro-intestinal tract is supplied by the vagus nerve, the nerves from the sacral portion of the spinal cord, the sympathetics and the plexuses of Auerbach and Meissner, also Keith's nodes. The vagus extends to the descending colon. The same portion of the gastro-intestinal tract receives its sympathetic nerve supply from the superior

mesenteric ganglion. "The muscular and glandular structures are activated by the parasympathetics and receive inhibitory impulses from the sympathetic."

"An equilibrium of action is maintained when the excitability of the parasympathetics and sympathetics equal each others, or when the excessive excitability in the one is still short of overcoming the excitability of the other."

Chronic appendicitis may produce chemical, mechanical or toxic irritation. From the symptoms produced by traction on an adherent appendix we are led to believe that mechanical irritation stimulates the parasympathetic nerve supply. The symptoms of a recurrent attack of appendicitis bear out the statement by Pottenger that "toxins stimulate the sympathetic nerves."

The symptoms produced by chronic appendicitis are reflex symptoms, except the tenderness of the appendix or an inflamed viscus to which it is attached; this accounts for the difficulty in making a diagnosis—and enables us to understand why chronic appendicitis causes indigestion. Irritation in the appendix is most frequently reflected to the stomach and duodenum, if the impulse is transmitted by the vagus it may cause cardiospasm or pylorospasm, hypersecretion and increased peristalsis; manifested by pain, a sense of fullness and sour stomach. Next in frequency the terminal ileum, cæcum, ascending and transverse colon are affected.

If the circular muscles receive the greater impulse we may have contraction and increased secretion with a dilated condition and delayed contents above the constriction; producing stasis, decomposition and fermentation; manifested by fullness, pain or discomfort and constipation; or if the longitudinal muscles receive the greater impulse we may have increased peristalsis and secretion; manifested by diarrhoea and mushy stools.

If the sympathetics are stimulated more than the parasympathetics we may have stasis of the main viscera with contraction of the sphincters, decreased secretion and increased absorption; manifested by slight rise in temperature, headache, lassitude, irritability, weakness, constipation, a dead heavy feeling in the abdomen with or without distention and a general miserable condition. The symptoms may be constant companions, frequent visitors, or occasional unwelcome guests. They may be very mild in type or of considerable vigor. Ordinary diet and exercise have but little effect in relieving or causing the symptoms, while imprudence in either may bring on an attack.

The symptoms can be briefly stated as colicky pains, acid stomach, gaseous distention, constipation, headache, lassitude, irritability, nervousness, general weakness, despondency, and more or less rigidity of the muscles in the lower right quadrant.

DIAGNOSIS.

Remembering the fact that indigestion is more often a symptom of trouble outside than inside the digestive tract makes us more careful in searching for the cause. A full history past and present is essential. A thorough examination of the patient is imperative. The abdominal examination should be last and exhaustive. Auscultation ascertains the rate and rhythm of peristalsis. Percussion demonstrates the presence or absence of solid or liquid masses and the extent of tympany: by the different notes we can usually outline the stomach, intestines and colon. Palpation is a most valuable ally in diagnosing abdominal trouble; by it we recognize rigidity in the abdominal muscles, in thin abdomens we can often feel the constricting spasms in the intestines and the distended portion above them. We can feel the violent peristaltic waves passing under the hand; we can bring out the tender point by pressure; we can feel and often empty a stagnant cæcum.

X-ray examination in chronic indigestion is most valuable and for a correct diagnosis often indispensable. The points upon which I rely most in making a diagnosis of chronic appendicitis as a cause of indigestion are these:—

1. A history of an attack of colic or pain in the lower right quadrant, diagnosed or undiagnosed as appendicitis.

2. Reflex types of indigestion.
3. A palpable tender cæcum with some rigidity of oblique, transverse and psoas muscles in lower right quadrant.
4. Recurrent attacks of so-called biliousness in adults and acidosis in children, with a tender palpable cæcum.
5. The above symptoms, plus x-ray confirmation and diagnostic exclusion of everything else that could reasonably cause the trouble.

A positive diagnosis of chronic appendicitis is the most difficult task undertaken by the physician or surgeon.

TREATMENT.

The only cure for appendicitis is surgical but surgery is not always advisable. We must remember that the nerves involved in indigestion caused by any chronic condition are sensitive for a long time after the cause has been removed. If we are reasonably certain that the appendix is the offender in a child by all means remove it. There are many brilliant examples of success in appendicectomies for chronic indigestion in children, some in adults and even in old people. Complications, the general condition of the patient and the type of patient often make us hesitate to advise an operation.

Regulation of diet, exercise and general advice as to living will often guide the chronic appendicular bark through the troubled waters of a long journey to a safe haven from which some other malady will finally collect the ticket for eternity.

An Address on Recent Aids in the Diagnosis of Some Common Disorders.

By T. C. HUNT, B.M. (Oxf.), M.R.C.P. (Lond.).

(Abstract from *The Lancet*, October 12th, 1929, Vol. CCXVII, p. 751.)

INDIGESTION.

I SHOULD like to say a few words about the differential diagnosis of some of the causes of indigestion, with particular regard to the so-called functional dyspepsias. The common type of patient, most usually a woman, who has abdominal symptoms suggestive of perhaps a gastric ulcer, but in whom we feel confident that a "neurosis" is the true cause, may present great difficulty in diagnosis. Often enough the general behaviour of the patient is characteristic and the pain is usually one that gets worse on going to bed, but never wakes her up once she has got to sleep; it is probably fairly true that "a neurosis never woke a patient." At the same time we often wish for physical signs or laboratory tests that can confirm our suspicions and exclude organic disease.

Of the physical signs of neurosis there is no one alone that can be of genuine assistance, and even a combination of many together can only increase the probability of a functional condition. Of these signs I may mention the exaggerated deep reflexes, brisk abdominals, absent palate reflex, and the evidences of various stigmata of degeneration such as asymmetries and minor deformities. To these is often added a condition of excessive vasomotor irritability or dermatographia, in which a wide red mark rapidly appears after quite gently stroking the skin with a blunt instrument. There is frequently a tachycardia and a low blood pressure which reacts abnormally to mild exertion. A further sign which is not commonly present in persons of "non-neurotic nature" is an absence of the corneal reflex, which is perhaps the most suggestive of all the multitudinous signs of "neurasthenia" that have been proposed.

All these signs, however, are notoriously unreliable and laboratory aids in investigating the case are of real importance. Of these I would especially mention the

value of an examination of the stools for occult blood, the finding of which definitely excludes a functional condition. It is so readily detectable that it should be looked for in all cases in which the possibility of ulcer or growth arises. In peptic ulcer intermittent bleeding is very common and in carcinoma of the stomach occult blood is seldom absent and often continuous.

The test is very easily carried out, and the patient need only exclude meat (and meat-extractives such as soup), fish, and green vegetables for two days from his diet. The simplest and most reliable technique is that of Gregerson, with the aid of benzidin tablets (benzidin 0.025 g. and barium peroxide 0.2 g.) obtainable from any chemist. One tablet or powder is dissolved in 5 to 10 c.cm. of strong acetic acid (50 per cent.), and a small particle of stool is rubbed up on the end of a match with a few drops of this solution. A positive result is shown by a green to deep blue colour appearing at once or within one to two minutes.

The use of these powders not only simplifies the test considerably, but excludes some of the fallacies of other methods of detecting occult blood. Indeed, A. G. Ogilvie considers that a blue colour obtained within 30 seconds is proof of occult blood in the stools entirely irrespective of the patient's previous diet. I realize that the test is well known, but I think it deserves more frequent application in general practice.

Test-meal analyses are, I am afraid, seldom of great assistance except in carcinoma of the stomach, pernicious anæmia, and duodenal ulcer. In the reflex and toxic dyspepsias of pulmonary tuberculosis, gall-bladder disease, renal disease, or chronic appendicitis, for example, the variations in gastric secretions are so diversely reported that assessment of their true significance is extremely difficult. In functional dyspepsia all types of test-meal results may be obtained.

There is one further test, which is old in origin but recent in its general utilization, which may be employed with advantage in such cases—namely, the *red cell sedimentation test*. In spite of all that has been written and claimed for this test, especially in relation to pulmonary tuberculosis, the evidence of recent years shows that its real and great practical value lies simply in the differentiation of organic disease from functional disorder. It is in no way specific for any one form of disease, although exaggerated claims have often been made in this respect. It is a test that determines merely the rate at which the red cells fall to the bottom in citrated blood, and even now, in spite of the immense amount of work that has been done upon it, we do not know the exact factors that control this rate of sedimentation. Four volumes of blood are mixed with one volume of 3.8 per cent. sodium citrate and the rate of sinking of the red cells in this dilution is normally slow. I will not describe the exact details of the test, the results of which are recorded either in terms of the time taken for the cells to reach a given height in a standard tube (Westergren-Fahraeus) or of the height reached at a given interval of time (Linzenmeier).

In organic disease, especially where any form of tissue destruction is occurring, the rate of sedimentation is considerably increased. It has now been completely demonstrated that in a given case rapid sinking of the red cells above the normal rate excludes the diagnosis of a purely functional disorder.* A normal rate is unfortunately by no means such certain evidence of the absence of organic disease. In suspected gastric neurosis or other functional disorders, therefore, a normal sedimentation rate is confirmatory only of the diagnosis, whilst on the other hand a rapid sedimentation must make us immediately turn to an organic cause for the symptoms concerned. In this somewhat limited field of usefulness this simple and inexpensive test has, I think, a definite value. The details may be found in any recent textbook.

*A rapid sedimentation is normal during the early months of pregnancy.

The Microscopic Examination of Fæces for Bacteria.

By S. W. PATTERSON, M.D., D.Sc., M.R.C.P.

(Abstracted from *The Lancet*, October 12th, 1929, Vol. CCXVII, p. 785.)

THE conditions of warmth, moisture, and pabulum obtaining in the intestinal tract are almost ideal for promoting the growth of micro-organisms, and a great variety of bacteria is to be found in the fæces. They are, however, really outside the body itself, and are to be regarded as essentially saprophytes, although under certain circumstances almost any of them may enter the body and become pathogenic. There are four great groups of bacteria normally appearing in the fæces; the coliform bacilli, the streptococci, the anaerobes, and the acidophile bacilli. The streptococci and acidophiles retain Gram's stain as do most of the anaerobes, while the coliform bacilli are decolorised by Gram's method. A generation ago Combe advocated the simple staining of a smear of the fæces by Gram's method, and drew inferences from the proportion of bacteria which retained the violet coloration to those which were decolorised and took up a counter stain. Although this procedure has not led to results of practical application, a variation in the proportion of the bacteria of the four groups named does nevertheless occur, and one of the chief factors influencing this variation is the diet taken by the patient.

INFLUENCE OF DIET.

The intestinal tract, which is sterile at birth, is soon found to contain bacteria. Normally about one-third of the dried fæces of healthy people on a mixed diet consists of bacteria. During the period of milk-feeding, the acidophile group predominates largely; but with the onset of mixed feeding, the bacterial distribution changes and soon resembles that of the adult, the coliform bacilli becoming the prominent group. The coliform and anaerobic bacilli preponderate with a high protein diet; whilst the *B. acidophilus* is increased on a high carbohydrate diet. Increase of streptococci follows an addition of glucose or cane sugar to the diet, and the numbers of viable streptococci are greater after a saline purge. Elimination of many putrefactive anaerobic bacilli and other proteolytic organisms, and reduction of the coliform bacilli, can be brought about by a lacto-vegetarian diet, with plenty of fruit and green vegetables, especially if lactose be added. Cultures of *B. acidophilus* may be given in milk to hasten the change of flora.

In addition to the normal inhabitants of the bowel, certain pathogenic organisms occur in disease, such as typhoid, dysentery, and tubercle bacilli. These will be dealt with before discussing the conditions under which the normal bacteria may cause disease.

THE TYPHOID-PARATYPHOID GROUP.

In the typhoid-paratyphoid group of diseases the bacteria may appear in the stools from the first week onwards, and are recovered in one-third to one-half of the cases. Though other methods of diagnosis are more reliable—such as blood cultures during the first ten days, and the Widal reaction after that—culture of the stools is useful as a control. Bacteriological technique has much improved as the result of the experiences of the war; it is now agreed that before a positive finding is reported the suspected organisms must not only conform to requirements in motility and fermentation of sugars, but also must be agglutinable by a standard serum. Typhoid and paratyphoid B bacilli, though less common than formerly, occur still in mild epidemics; paratyphoid A, an Eastern type, was more often met with during the war, brought by the troops coming from India. These diseases must be notified. The bacilli continue to be excreted in gushes for some time during convalescence, so that several negative reports at intervals should be obtained before the patient returns to ordinary life. Sometimes it happens that a patient, though apparently well, con-

tinues to pass enteric bacilli at intervals; he becomes a "carrier," and a source of unwitting infection of the rest of the community. Such a person should be isolated under medical supervision, and should be debarred from any occupation which entails the handling or distribution of foodstuffs. Unfortunately, in these cases, it is often difficult to get rid of the infection, which may continue for a long time in such places as the gall-bladder.

DYSENTERY BACILLI.

In cases of colitis due to infection with dysentery bacilli, the organisms can be recovered from the mucus in a large majority of the cases in the acute stages; in chronic cases they are rarely found. Indeed it may well be that bacillary dysentery is always an acute infection, though sometimes quite a mild one; and that a chronic colitis following an attack of dysentery is kept up by non-specific bacteria as a secondary infection. The laboratory report should differentiate between dysentery bacilli of the *Shiga-Kruse* and of the *Flexner-Y* types. The former infection is a serious affair, since the *Shiga* bacillus has a toxic effect on the nervous system as well as on the intestine. Nowadays a good antitoxic serum is available. Infection with *Flexner* dysentery bacilli is milder; it may be troublesome, however, and even fatal in infants, or in elderly or debilitated patients. There are at least five members of this *Flexner-Y-Hiss* and *Russel* type, and no standard serum is available. Eliminative treatment, for example by sodium sulphate, is the best.

A number of bacilli, not true dysentery, but capable of producing colitis, are grouped together as *paradysentery* bacilli, of which perhaps the best known are *Morgan's No. 1* bacillus in the summer diarrhoea of children, the *Sonne* bacillus associated with dysenteric symptoms, and the *Bacillus enteritidis* of *Gaertner* and *B. artryche* in food poisoning. The allied *B. supestifer* (hog cholera bacillus) is important for animals and probably sometimes for man. There are also others whose claim to be regarded as pathogenic is not yet accepted. These will be dealt with later.

TUBERCLE BACILLI.

A report of tubercle bacilli can only rarely be unexpected. Their presence in sufficient numbers to be detected in a routine examination will occur only when there is gross clinical evidence of chronic bowel trouble. In children with phthisis, in whom all sputum is swallowed so that none is available for direct examination, pus containing tubercle bacilli may be passed in the motions. In suspected cases of intestinal tuberculosis, special methods of concentration with anti-formin and inoculation of a guinea-pig may be required.

Cocci.

Staphylococci are not inhabitants of the intestine. When their presence is reported, a local infection of the lower bowel by abscess or fistula-in-ano should be sought for; otherwise it is a negligible contamination from the skin. *Streptococci*, on the other hand, form one of the important groups of the normal intestinal flora, and there are several varieties which may at times be pathogenic. The usual differentiation made is by their action on blood cells, so that they may be classified according as they produce a green pigment, or completely hæmolyse the blood corpuscles, or have no effect upon them. All three classes may be present in fæces. The non-hæmolytic one (*enterococcus*) is the commonest. It is usually not pathogenic, though it is reputed to be so at times, as a secondary infection following ulcerative states of the bowel. A variety of the *enterococcus* is believed by *Bargen* to be the causative organism in chronic ulcerative colitis; but this is not generally accepted by pathologists. The other two classes, green and hæmolytic streptococci, may also become pathogenic. If they invade the blood stream or tissues of the body, they may cause severe symptoms, but their presence in the fæces is not necessarily significant.

OTHER MICRO-ORGANISMS.

The vibrio of *cholera* may be found in epidemics in the tropics, but does not occur in these islands. *B. pyoryancus* (the bacillus of blue pus), *B. proteus* (a putrefactive bacillus often found in great numbers in watery offensive stools), *B. lactis aerogenes* (allied to *B. Friedländer*, the pneumobacillus), *B. faecalis alkaligenes* and *B. pseudoasiaticus* are rather harmless findings in the faeces, though possibly they may become pathogenic at times in other situations.

The other groups of faecal bacteria, anaerobic and acidophile, as well as the spirochaetes and yeasts—except the ray fungus of actinomycosis—are not important so long as they remain in the lumen of the bowel; though it may be expected that as our knowledge of the biochemical products formed by these organisms from food-stuffs increases, there will be some evidence found on which to form conclusions about a possible "intestinal toxæmia."

While one-third of the dried weight of normal faeces consists of the bodies of dead bacteria, these bacteria in the lumen of the bowel are really, as already mentioned, outside the limits of the body proper, and are as unlikely to gain entrance to the body, unless there is a breach in the mucous membrane, as are skin organisms without some damage to the skin epithelium. Such a break in the mucous membrane of the bowel occurs in any abrasion or ulcer, and there is no doubt that a secondary infection of dysenteric and tuberculous ulcers takes place with the ordinary cocci and bacteria of the bowel. Even when the site of invasion is not obvious, we know that a septicæmia with colon bacilli may occur, and that these are often excreted by the kidney causing irritation and inflammation of the urinary tract. Just before death, too, the blood is often invaded by bowel organisms, which can be recovered in blood culture; being a terminal state only, this septicæmia of intestinal organisms is not important, as by the time it sets in the bowel wall has probably lost its normal protective power.

CRITERIA OF PATHOGENICITY.

These conditions are, however, exceptional. What importance should be assigned to the bacteria which remain in the lumen of the bowel? It must be noted that the media used for culture of micro-organisms are artificial ones; though selective for some bacteria, they may even inhibit others. The amount of growth on culture media may bear little relation to the numbers of bacteria present in the faeces, or to their pathogenicity. Too much emphasis should not be laid on an apparent increase in numbers, such as an excess of streptococci; it has been shown above that great variations in numbers of streptococci occur with change of diet, and of the consistency of the stools. In pernicious anaemia and other conditions with sub-acidity of the gastric juice, there is a great numerical increase of the normal inhabitants of the bowel, *B. coli*, streptococci and especially the anaerobe *B. welchii*. But there is no evidence that these organisms differ qualitatively from those found in healthy persons, or that any individual type of organism is specifically related to pernicious anaemia. It is necessary, too, to avoid the fallacy of treating the patient for such conditions as the presence of coliform bacilli, which are atypical in having a delayed power of fermenting lactose. The usual *B. coli* rapidly produce acid and gas in lactose media, whilst most of the known pathogenic Gram-negative bacteria do not show this reaction with lactose in ordinary media. There is an intermediate group which ferments lactose after an interval of several days some of them may even produce so much ammonia from peptone digestion that an acid reaction never appears which are classed alternatively as *para-dysenteric* or *para-colon* bacilli. A few of these are of known pathogenicity, a few of known harmlessness; there is little evidence that the majority of them exert a harmful action on the animal body. The quality of delayed fermentation of lactose is not therefore significant. A further group of these colon bacilli is

found to grow in the presence of normal active serum; some even hæmolyse red blood corpuscles. These serum-resistant and hæmolytic *B. coli* may be pathogenic, but we have no certain evidence on this point. The same is true of hæmolytic streptococci. Their ability to live on blood, digesting and destroying the red corpuscles, makes them, at any rate, potential parasites, and, if they are found elsewhere in the alimentary tract at the roots of teeth, in the crypts of tonsils, or in the discharge from nasal sinus infection, as well as in the faeces—their possible importance cannot be denied. But if the evidence we have of the pathogenicity of these groups of bacteria is doubtful, evidence of their relevance in a particular patient is usually unattainable; the presence of any sort of specific immune body in the patient cannot be demonstrated by serological tests.

VACCINES FROM FÆCES.

The value in treatment of vaccines made from the faeces, though widely assumed in this country, is not proved by bacteriological criteria, and does not rest on the same scientific basis as, for example, typhoid preventive inoculation, or the treatment of diphtheria and tetanus with serum. Nor has it the support of solid clinical proof, such as that of the value of vaccination against smallpox. It rests mainly on clinical impressions, which, as time goes on, may need to be revised, or, at the least, defined and classified.

In view of the great difficulties which confront anyone attempting to assess the possible pathogenic significance of faecal organisms, therefore, no clear indications can be found for their use in vaccine-therapy. Antibodies to them may be formed by a patient into whom they are injected, but we have no means of knowing whether these have any specific action or are likely to help the patient in resisting his disease. Although vaccines have a proved place in bringing about protection against subsequent infection, their role in treatment is by no means securely founded. Until further positive evidence is accumulated, therefore, we have no warrant for using any but those derived from organisms with known pathogenic action; the promiscuous use of vaccines from other faecal organisms is unlikely to lead to useful results.

The Relation of Ear Conditions to Bathing.

By W. I. DAGGETT, M.A., M.B., F.R.C.S.,
and

R. COVE-SMITH, M.A., M.B., M.R.C.P.

(Abstracted from *The British Med. Journ.*, August 17th, 1929. No. 3580, p. 296.)

THE daily papers are taking an increasing interest in the health of the populace, yet insufficient attention has been drawn to the precautions necessary for those who wish to avoid the inconveniences which may result from careless indulgence in swimming. Many medical men allow their patients too much licence in this direction, and fail to pay attention to small details which would increase the comfort of all.

It is obvious to those who attend out-patients in any large ear, nose, and throat clinic that a great number of acute aural conditions develop as the result of bathing. Moreover, such conditions may have dangerous sequels. For a long time at King's College Hospital we have had a notice placed in the out-patients' department which warns patients against bathing without leave from the surgeon.

From the point of view of the ear, nose, and throat surgeon the bathing community can be divided into (1) healthy persons; (2) those with septic nasal conditions (including the common cold); (3) those with a perforation of the tympanic membrane; (4) those with recurrent dermatitis or furunculosis of the external auditory meatus.

As regards persons in normal health, the public has a vague idea that water introduced into the meatus may be dangerous, and cotton-wool and other substances are used to prevent this. In such persons the

entry of water does no harm, though it may give rise to several unpleasant symptoms. Among these are deafness and tinnitus following immersion. This is due to the swelling of wax and occlusion of the meatus, or to water collecting behind an accumulation of wax where it may remain for some time. Another cause is the foolish practice of drying the ears with the rolled-up corner of a towel, thus pressing down against the drum any wax that may be in the meatus. Some may complain of a transitory earache due to cold water impinging on the drum, but this symptom should not be "passed off" without thorough examination lest acute otitis media be the cause. We have not yet met a case of vertigo; in fact, this is hardly to be expected, as cold water enters each meatus with equal caloric stimulus to both labyrinths, so that the labyrinthine equilibrium remains undisturbed. The possibility of the occurrence of such a symptom must, however, not be overlooked, for it could occur if one meatus was occluded and the other patent.

Too often acute otitis media, with or without dangerous complications, occurs in the healthy swimmer. This is due to the entrance of infected water into the Eustachian tube and middle-ear tract. Public swimming baths and "town" rivers are great sources of danger. Those who bathe in the sea or in mountain streams are usually exempt from trouble. The healthy Englishman is fond of swimming, and in the large towns public baths afford the only facility. There is therefore a crying need for those in authority to render the public baths as safe as possible. It is essential that constant inspections should be undertaken. The problem is a difficult one, for disinfectants cannot be introduced in sufficient concentration without rendering bathing irksome. Calcium chloride is used in many places; it imparts a somewhat unpleasant taste to the water, and usually gives rise to a mild conjunctivitis. Naturally water is not rendered safe by this means, but if continuous filtration is carried out as well the risk is minimized. It is interesting to note that we have not been able to trace more than an isolated case of ear trouble attributable to bathing in the Camberwell baths, where this method is practised. In far too great a proportion of public baths the water is not changed often enough, whilst scouring of the empty bath is inefficiently carried out. It should be made compulsory for bathers to wash with soap before entering; in Germany this is an almost universal practice. Again, it is a bad principle that bathers should be allowed to come in straight from the streets and tramp along the sides of the bath in their grimed boots. All this filth must sooner or later find its way into the water.

The present facilities for bathing will not be revolutionized for some time, so we must consider what type of swimmer tends to develop acute otitis media and how the risk may be minimized. As a rule it is the badly taught, inexperienced swimmer who suffers most and becomes the victim of an "acute ear." Correct breathing is essential to prevent the entry of infected water into the Eustachian tubes, and it is here that the tyro fails. The practised swimmer fills his lungs at regular intervals through the widely opened mouth, keeping the soft palate raised and thus shutting off the nasopharynx. In fact, many swimmers of repute continually have the mouth open, even under water, gradually blowing air out until they need a fresh inspiration, when the head is turned clear of the water and air taken in through the mouth. The inexperienced swimmer fails to regulate his breathing properly, draws the water into his nose, chokes, and swallows; this last action opens up the Eustachian tubes and water is allowed to enter. For the same reason it is unwise to "duck" suddenly or to push a friend in unawares; proper inspiration is difficult in such crises. Jumping in from a high board should not be practised without holding the nose, as the sudden inrush of water into the nostrils may force some into the sinuses or into the Eustachian tubes.

It will be argued that thousands of people in normal health bathe regularly without precautions and come to

no harm; nevertheless, the risk is there, and correct breathing should be taught.

The second class, those suffering from septic nasal conditions (including the common cold), should not be allowed in public baths. Not only do they spread infection, but any water entering the nose may carry infection backwards into the nasal accessory sinuses or Eustachian tubes. Swimming is dangerous in the same way as the pernicious habit of sniffing salt and water up the nose to relieve the common cold.

Patients who have a perforated tympanic membrane often ask whether bathing is permissible. Whether or not there is discharge the answer should be an emphatic "No." Those in whom the discharge has ceased will almost certainly become reinfected with consequent exacerbation of old trouble; whereas those with an active discharge will contaminate the water and lay themselves open to the risk of added virulent infection and acute symptoms supervening on the chronic. The professional or expert swimmer may possibly be excepted if the ear has been dry for two years or more, although the perforation has not healed, but every precaution must be taken as regards breathing and against the entry of water into the meatus. No form of precaution is "foolproof," though a small piece of wool impregnated with vaseline and laid in the meatus may serve a useful purpose. Better still, a thin piece of wool may be laid over this and kept in place with collodion. A successful radical operation, one year after complete healing, places the patient in Class 1 (healthy persons) as regards bathing. Patients with acute or chronic meatal eczema or recurrent attacks of meatal furunculosis are best advised not to bathe, for exacerbations are only too common.

Many swimmers who make a practice of diving into deep water complain that when they go beyond a certain depth they get a violent ringing in the ears. This is as a rule temporary; it is partially due to prolonged holding of the breath and partially to increased pressure on the tympanic membrane and stapes. Should it persist it will probably be found that there is some degree of Eustachian obstruction and retraction of the tympanic membrane and that politizerization will relieve the noises.

Reviews.

RECENT ADVANCES IN CARDIOLOGY.—By C. F. Terence East, M.A., M.D. (Oxon.), F.R.C.S. (Lond.), and C. W. C. Bain, M.C., M.B. (Oxon.), M.R.C.P. (Lond.). London: J. A. Churchill 1929. Pp. VIII plus 342 with 12 plates and 57 text figures. Price, 12s. 6d. net.

THERE can be no doubt that the *Recent Advances* series of medical books has obtained a degree of popularity which it deserves.

The science of cardiology has advanced with immense strides during the last decade. This advance has been due to the previous work, experimental and clinical, that was carried out by the famous pioneers of modern cardiological methods. The heart specialist of to-day has means of investigation that were unknown to his teachers. Not only can he use these methods when necessity arises, but, what is more important, his clinical acumen and personal experience are now based on facts that have been proved to be correct by scientific means and experiments.

He is no longer working in the dark, nor is he attempting to judge the efficiency of the heart only by the deceptive sounds that he hears with a stethoscope and the very variable symptoms that are associated with such an investigation.

It is an explanation of these modern methods that this book describes, and we may say at once describes with the greatest success. The first two chapters deal with myocardial infarction and angina pectoris. The differentiation of these important diseases is clear and all recent knowledge of the symptoms of thrombosis of the coronary arteries is included.

A chapter entitled, "Some evidences of Myocardial Disease," is very practical and the value of the electrocardiograph is explained. Disorders of rhythm are adequately described. A considerable portion of the book deals with circulatory failure in all its aspects. This is extremely interesting and embodies all the recent knowledge that has accrued from physiological experiments and clinical observations. The chapter on the treatment of heart failure is practical and sufficient. The condition of the heart under abnormal conditions such as infections, anaesthesia and thyroid disorders and pregnancy is considered, and the methods which may be expected to help the heart under these circumstances are described. The action of digitalis on the heart receives a chapter to itself and is as clear as any that the reviewer has seen on this rather complicated subject. The modern methods of cardiac radiography are explained and the principles of electrocardiographic examination are summarised. Abnormal blood-pressure and its significance receives rather scanty treatment in the final chapter.

There is no other book of this size which explains the present position of cardiology so simply and adequately. As with all the others of this series the printing, index and bibliographies leave nothing to be desired.

This volume should be in the possession of all medical men, and perhaps those who received their medical education more than ten years ago will find it of the most value.

H. H.

HAEMODYNAMICS: THE MECHANISM OF VENOUS CAPILLARY AND LYMPHATIC FLOW; OEDEMA; AND INJECTION TREATMENT OF VARICOSE VEINS.—By P. B. Kittel, F.R.C.S. London: H. K. Lewis and Co Ltd. 1929. Pp. XI plus 195 with 3 plates and other illustrations. Price, 10s. net.

THE title and subtitle of the book are sufficiently explicit as to the nature and scope of Dr. Kittel's treatment of the subject. The first two chapters form an introductory section in which the physical signs of varicose veins, the action of valves in veins and compensatory dilatation are lucidly sketched.

Varicose eczema and ulcers are known according to the author's observation to be confined to the lower limbs and "in about 80 cases out of 450 at the hospital, which have had skin lesions of one sort or another peculiar to varicose veins, the highest point where eczema has been found has been the tubercle of the tibia, and an ulcer has not been observed much higher than about the middle of the shin."

When the lesions (which are inferred to be part of a condition in which varicosity is the commonest feature) are joined up through proximity and development the whole skin is seen to be destroyed, though initially they are localized as eczemas and confined to the obstruction of only epidermal cells.

Another digression upon venous and capillary flow discusses the relevant points of blood circulation for the proper comprehension of the subsequent chapter on oedema and lymphatic oedema.

The last part of the book deals with modern researches on the flow in varicose veins and of the experiments of the author in the treatment of this condition, and of varicose eczemas and ulcers, with the results obtained by the action of various drugs in these cases.

A great amount of original matter from the author's researches is incorporated in the volume.

All interested in the pathological condition of venous and lymphatic stasis will find this illuminating contribution a most helpful addition to the literature.

S. S. R.

A NEW TREATMENT OF TUBERCULOSIS.—By P. Hulliger. London: H. K. Lewis and Co. Ltd. Pp. X plus 146. Illustrated by 40 photographic and radiographic plates showing cures of cases of tuberculosis of the lungs and bones. Price, 8s. 6d. net.

The author claims that his treatment, as opposed to all other treatments for tuberculosis, is specific. This claim he bases upon the reaction-producing pro-

perties of his drug. His last chapter is entitled "And our exact formula?" In this chapter he says:—"Evidently we shall give our exact formula some day. But before giving it we desire the medical profession to acknowledge our results and our reactions, and to state, 'officially' whether our treatment is specific for tuberculosis or not." Here the writer leaves us in the tantalising position in which the serial story writer leaves his readers with the foot-note "to be continued in our next;" but he does not even state when the "next" is to be.

One is forced to the conclusion that in spite of the M. D. at the end of the author's name he does not live up to the rule set before the medical profession of avoiding the advertisement of secret remedies.

The results which he illustrates, though apparently striking, still leave doubts in the critic's mind, and these doubts are by no means diminished by the tone of the whole book.

This new treatment may or may not have a great deal in it; but if it has it is certainly up to the discoverer, provided he believes in it himself, to disclose what his remedy is. Till then more favourable judgment must be suspended.

E. M.

INTERNS' HANDBOOK.—By Members of the Faculty of the College of Medicine, Syracuse University. Under the direction of M. S. Dooley, A.B., M.D. London: J. B. Lippincott Company. Pp. XIX plus 254. Price, 12s. 6d. net. Obtainable from Messrs. Butterworth and Co. (India), Ltd. Calcutta: Price, Rs. 9-6 net.

A HANDBOOK for interns in which an attempt has been made briefly to state the clinical methods in practically all branches of medicine. Most of the information is given in a tabulated form and is therefore easy of reference. It will be found useful not only by interns but also by the general practitioner. The small size of the book is an advantage in that it can be carried about in the pocket.

P. B.

BIOLOGICAL REVERSION AND HIPPOCRATIC ANATOMY.—By H. Higgins M.A., M.R.C.S., L.R.C.P. London: H. K. Lewis and Co., Ltd. 1929. Pp. IX plus 149. Price, 7s. 6d. net.

THE book under review is an eminently readable digression into subjects medical, psychic, metaphysical, poetical and other themes equally interesting. To define the scope of the work in the author's words "Biological reversion is a clinical method designed to define and rectify the consequences of chronic toxæmia." A detailed anatomical analysis is made of the skin, the subcutaneous tissues, connective tissues and muscles. The liabilities of under-nourished intoxicated tissues with faulty function and lymphatic stasis are then compared with the assets—normal tissues and normal function. Toxæmia is eliminated after a search for focal sepsis and the intestinal traffic restored by the devices described in the text. Regeneration is promoted locally by mechanical accelerated nutrition and generally by clinical metabolism. The mechanical treatment restores lymphatic circulation in a predetermined order and in addition provides useful indications for directing treatment by means of biological reactions excited by the manipulations."

This volume, treating of everything in general and of nothing in particular, should provide interesting reading to doctor and layman alike during leisure hours.

S. S. R.

PRACTICAL LOCAL ANÆSTHESIA AND TS SURGICAL TECHNIC.—By R. E. Farr, M.D., F.A.C.S. Second Edition. Thoroughly Revised. London: Henry Kimpton. 1930. Pp. XXIII plus 611 with 268 engravings and 16 plates. Price, 42s. net.

It has always been the aim of surgery to find out some means of abolishing pain during operative manipulations, and in old days various plans were adopted to attain this. Real advances in this direction were made quite recently. Anæsthetics have enabled

surgeons to tackle almost every region of the body, and instead of operations being hurried over they are now undertaken with much more deliberation and accuracy.

In the present volume the author deals with that form of anaesthesia which is obtained by paralysing the sensitive nerve-endings in the immediate neighbourhood of the operation by means of some agents or by temporary suspension of the conductivity of the main nerve trunks supplying the affected area. With the increase of interest of surgeons in local anaesthesia, many recent advances have been made in this realm and these have been carefully considered in the body of the book. The types of the different methods of administering local anaesthesia are dealt with in detail. The chapter dealing with the anatomy of the sensory nerves is a valuable contribution and it helps the reader to gain clear conception of the subject. The author has spared no pains in making himself clear with the help of engravings and plates. Local anaesthesia in surgery of all the regions of the body is described separately and we consider this a very valuable guide to surgical practitioners.

The whole book is written in a very convincing style and the author has presented the subject of local anaesthesia and its surgical technic to students and practitioners in such a way that there is little difficulty for them in grasping the idea and applying it in actual practice.

R. N. C.

THE TREATMENT OF VARICOSE VEINS OF THE LOWER EXTREMITIES BY INJECTIONS.—By T. H. Treves-Barber, M.D., B.Sc., with a foreword by H. W. Carson, F.R.C.S. Bristol: John Wright and Sons Ltd. 1929. Pp. 120. Illustrated. Price, 6s. net.

The injection method of treatment of varicose veins has been greatly appreciated by both surgeon and patient during recent years. There can be no doubt that the older operations of excision, however carefully and skilfully performed, very seldom resulted in a permanent cure and in all cases meant a lengthy convalescence and permanent disfigurement.

This little book is an epitome of the author's experience extending over several years, and therefore gives very practical advice and instruction. The opening chapters deal with the anatomy, pathology and symptoms of varicose veins and there is a very useful classification.

The main part of the book describes in detail the technique of the injection. The author invariably uses a sodium chloride solution and states that it has always given him the most gratifying results. Theoretically no solution could be safer, or simpler to prepare.

In India every house surgeon gives numerous intravenous injections, and frequently in difficult cases, so the actual operation should present no difficulty to most medical men here. The author is probably not exaggerating when he states, "No other branch of surgery can claim to have acquired, in such a short space of time, more satisfactory or more brilliant results than the sclerosing method for the obliteration of varicose veins."

Every surgeon in charge of a *mofussil* hospital and indeed all who have to perform minor operations should be in possession of this book. It will enable them to benefit their patients in a simple and efficient manner.

H. H.

AIDS TO ORTHOPÆDIC SURGERY.—By Mr. Erlo A. Crook, M.Ch. (Oxon.), F.R.C.S. (Eng.). London: Baillière, Tindall and Cox. 1929. Pp. VIII plus 232 with 17 figures in the text. Price, 3s. 6d. net.

ANOTHER addition to the *Aids* series. It will be found useful by students for quick revision before the examination. All important symptoms and methods of treatment are briefly stated.

P. B.

A GRAPHIC GUIDE TO ELEMENTARY SURGERY.—By Prof. Dr. Th. Næggeli, Bonn. Translated by J. Snowman, M.D., M.R.C.P. London: John Bale Sons and Danielsson Ltd. 1929. Pp. 208 with 322 illustrations (mostly coloured). Price 12s. 6d. net.

AN excellent little book on elementary surgery, written and illustrated in a most interesting and original way. The word graphic describes the method of illustration very well. Each one of its 322 illustrations is highly practical and to the point, conveying a clear idea not only of clinical methods in surgery but also of various pathological processes.

The book will be found very useful both by students and teachers of surgery and none of them should be without a copy.

P. B.

THE CHEMISTRY AND BACTERIOLOGY OF PUBLIC HEALTH.—By C. L. Dunn, C.I.E., D.P.H. (Lond.), Lieut.-Colonel, I.M.S. and D. D. Pandya, D.P.H. (Cant.), Rai Bahadur. Calcutta: Butterworth & Co. (India), Ltd. 1929. Pp. XI plus 412. Price not stated.

It is perhaps a misfortune that most textbooks on Public Health and allied subjects have to be written either to a syllabus or for examinations. This fact rather cramps an author's style and limits originality; the chemistry, bacteriology and entomology of public health and preventive medicine in the tropics are perhaps capable of a much more expansive treatment than has been given here, and the authors might take up the suggestion later to write a book dealing specifically with chemical, bacteriological and entomological problems of public health in the tropics. As the authors state in their preface, however, the book is primarily intended for Part I of the D. P. H. examination and for routine work. This object they have successfully achieved.

The descriptions of methods throughout the book are clear and unambiguous and great care has been taken to keep matter and references up to date. The work of Williamson and Senior White on the effect of the chemical constitution of natural waters on anopheline breeding is noticed, and the important work on the differentiation of antigens of the O and R types indicated. We were disappointed to find no reference to Clemesha's work on the bacteriology of water in the tropics. Whatever opinions one may hold, this is work with which every public health student in the tropics should be acquainted.

The book will be found very useful both to students and workers in Public Health, and is recommended to all as a good treatise and reference book. The printing and binding are satisfactory.

A. D. S.

SERUM DIAGNOSIS BY COMPLEMENT FIXATION WITH SPECIAL REFERENCE TO SYPHILIS—THE PRINCIPLES, TECHNIQUE AND CLINICAL APPLICATIONS.—By John A. Kolmer, M.S., M.D., Dr. P.H., D.Sc., LL.D. London: Baillière, Tindall and Cox. 1929. Pp. XIX plus 583, with 65 text figures. Price, 31s. 6d. net.

DR. KOLMER is well known as the writer of very numerous papers on serological subjects, and in particular as the author of a special Wassermann technique which undoubtedly forms a contribution of permanent value. The author, while disclaiming any intention of reviewing the enormous literature of the Wassermann reaction, here summarises the results of nine years' clinical and laboratory investigations into this subject. His most interesting monograph deals with the application of complement fixation tests not only in syphilis but over a wide range of diseases.

Part I is devoted to a presentation of the principles of serum hæmolysis and complement fixation. In Part II the principles of technique are discussed, so that it may be understood how an extremely sensitive system can be combined with a high degree of specificity. So much harm has been done by defective

Wassermann work that the author has sought to discover and eliminate the various sources of error. In Part III the author gives detailed descriptions of his own techniques in the hope that other workers may follow them *exactly*. There has undoubtedly been too great a tendency to modify complement fixation techniques before the possibilities of the technique itself have been fully explored. Part IV is devoted to practical applications of the complement fixation method in the serum diagnosis of syphilis, tuberculosis, gonorrhoea, glanders, typhoid fever and many other diseases. While much more than a laboratory manual, the work will, on account of its highly technical nature, appeal mainly to serologists, the more so as the many most valuable practical hints are in our view its strongest part.

Dr. Kolmer writes with authority on complement fixation and his book is a valuable addition to the literature of the subject. We unhesitatingly recommend it to laboratory workers and to those clinicians, both in the field of human and veterinary medicine, who desire to familiarise themselves with the fundamental principles on which these tests are based and their clinical meaning under various sets of circumstances. The book is well got up, printed in clear type on good paper, and there are numerous clear illustrations, more particularly of methods of bleeding and of special apparatus.

R. B. L.

HUMAN HELMINTHOLOGY.—By E. C. Faust, Ph.D. London: Henry Kimpton. Pp. XXII plus 616. Illustrated with 297 engravings. Price, 36s. net.

THIS is by far the most comprehensive publication on helminthology as it effects the human host that has ever been produced, and it brings the existing knowledge of the subject right up to date.

The book deals with all phases of the subject, the description of a worm and its life history being followed by paragraphs on pathology, clinical symptoms, diagnosis, treatment and prophylaxis. The purely zoological portion of the book appeals to the reviewer as the best, the pathology and treatment being not so fully dealt with in many cases.

Although a very useful book of reference for the medical practitioner it is, on the whole, more a book for the zoologist, and the introduction of numerous new superfamily and family names with their definitions will be of little interest or value to the clinician, and will serve rather to confuse the mind of one not a specialist in zoology. It is doubtful whether the formation of higher groups is a sound proceeding in a book that deals with a very limited number of species in a given group, for it has always seemed to the reviewer that the more limited the number of species being dealt with in a classification, the more imperfect is such a classification when applied to the Class as a whole.

Three and a half pages are devoted to a list of parasites from human hosts, each name being followed by "The pathological designation for infection with the parasite." This appears rather unnecessary especially when it leads to such a condition as infection with *Braunia jassyensis*, and which has only been recorded once, being designated "brauniasis jassyensis." It is doubtful if this nomenclature will be followed to any extent by the medical profession, for it will possibly lead to some of the confusion that exists in zoological nomenclature being transferred to medical science. One case at least of this already exists where filariasis is now designated wuchereriiasis by some modern writers. This alteration in a well established name seems unnecessary, as although the generic name of the causative organism has been changed the worm is still a filaria in the broad sense, and it seems more reasonable to confine the pathological name of infection with this worm to the family or superfamily root followed by the specific name (e.g., filariasis due to *Wuchereria bancrofti*), which will be much more comprehensible to a medical man who is not a zoologist as well.

A few rather terrifying and difficult phrases to understand occur in the book such as, "Piscivorous amniotes serve as the definitive hosts" in referring to Ophiorthosis, and it is rather unnecessary, as the next sentence says, "Some members of the superfamily live in mammals, others in birds....."

There is a useful list of references at the end of each chapter indexed under the names of the parasites to which they refer; although closer to the subject matter of the book wherein they are quoted they are not so rapidly accessible as in the usual place, at the end of a book, for one has often to turn over numerous pages to find the end of a chapter.

Section 4 deals with the laboratory side of the subject in a general way and it gives a useful outline of the approved methods of examining and preserving helminths and their eggs. The final chapter of this section is devoted to brief descriptions of the important intermediate hosts of worms. As the author says, this is only a bare outline, and that is all that can be given in a book of this size, but it should prove useful in enabling one who is not a zoologist in placing any given host in a family or even in a genus; the specific determination will always have to be left to the specialist.

On the whole the illustrations are well chosen, and there are many diagrams of life histories which give the salient points at a glance, and which will be of great assistance to beginners.

The book is well printed and the number of errors in type setting are remarkably few.

It is considered that it is a valuable publication to anyone dealing with purely human helminthiasis, and the only real criticism is that the considerable space devoted to pure zoology has made the book rather expensive for a practitioner who only occasionally has to deal with helminth infections, and who is only interested in the clinical and therapeutic side of the subject.

P. A. M.

MEDICAL JURISPRUDENCE.—By M. A. Kamath, M.B. & C.M. With the assistance of V. Vishwanathan, L.M.P. Third Edition (revised and enlarged). Calcutta: Butterworth & Co. (India), Ltd. 1929. Pp. IX plus 197. Price, Rs. 4.

THIS is a valuable epitome of the main facts of medical jurisprudence. The authors have revised and enlarged the present edition and a useful chapter dealing with the unconscious patient has been added.

Attention has been rightly drawn to the fact that available statistics regarding ossification refer to Western countries and it is reasonable to infer that epiphyse unite much earlier in India.

The appendices are of much help to the general practitioner as they deal with the method of holding post-mortem examinations, the issue of wound, lunacy, post-mortem and physical fitness certificates, and the method of sending viscera to the Chemical Examiner.

The presentation of facts is concise and clear but uncritical. The book remains as before a useful pocket textbook to help students through their examinations.

B. G. M.

ULTRA-VIOLET RAYS IN THE TREATMENT AND CURE OF DISEASE.—By Percy Hall, M.R.C.S. (Eng.), L.R.C.P. (Lond.), Fourth Edition. London: Messrs. William Heinemann (Medical Books) Ltd. 1929. Pp. XVIII plus 248 with 57 illustrations. Price, 12s. 6d. net.

It is only two years since the last edition was published. Since then the science of actino-therapy has advanced steadily, and as the author suggests, perhaps the most encouraging sign of the times is the realization that ultra-violet radiation should be administered only by the qualified and experienced.

This latest edition contains two new chapters. One on the vexed question of lamps for home use. Here it is pointed out that many of the lamps designed for the purpose are therapeutically inactive. Minute and regularly repeated doses are beneficial in the dull winter

months, but they should not be used indiscriminately, to the exclusion of the medical attendant, as vague ill health frequently precedes serious disease, and the delay involved may be disastrous.

The other chapter deals with dosage, and certain broad outlines are given to act as a guide to the operator. This should be very useful for the beginner, but it is pointed out that each patient is a law unto himself, and the safest plan is to begin with small doses and gradually increase them up to the limit of tolerance.

This little volume is now thoroughly up to date, easy to read, well illustrated and devoid of futile packing. We can thoroughly recommend it to anyone interested in the subject.

J. A. S.

DENTAL LOCAL ANÆSTHESIA. OUTLINES OF DENTAL SCIENCE, VOL. XIII.—By John James, L.D.S., R.C.S. (Eng.). Edinburgh: E. & S. Livingstone. 1929. Pp. 127 with 15 illustrations. Price, Rs. 5-10 per copy. Obtainable from Messrs. Butterworth and Co. (India), Ltd. Calcutta.

THIS is a concise book on dental local anæsthesia. The subject, it seems to us, has been shortened, at the expense of clearness. We feel that in such a short book, more illustrations would have been better. The instruments, the drugs, the various methods of injection and complications and contra-indications have been dealt with in a concise manner. We do not quite understand why the author recommends inserting the needle midway between the neck of the tooth and the apex of the root, in submucous anæsthesia. We feel that the majority of practitioners would vote for the universal method of inserting the needle at the apex of the root.

The book is a handy volume for the dental student. The last chapter entitled "conclusion" should be read by all students as it puts succinctly the viewpoint of an experienced practitioner and therefore should be thoroughly digested by all students and new practitioners.

The book is well got up and printed and does credit to the well known publishers.

R. A.

ANNALS OF THE PICKETT-THOMSON RESEARCH LABORATORY. Vol. IV, Parts 1 and 2. London: Baillière, Tindall & Cox. 1928-1929. Pp. XV plus 494, with 18 plates and 2 figures in the text. Price 42s. net per volume. Post free.

THE first monograph consists of an historical review of researches on the rôle of streptococci in rheumatic fever, by David and Robert Thomson. They first, appropriately, give a résumé of the researches on the various organisms which have come under suspicion as the cause of the disease, from 1885 to the present day. Numerous organisms have been suspected, but the streptococcus has been predominant throughout the whole period. They then deal with the blood changes, the vaccine treatment and the histology of the disease, its association with tonsillitis, and various other aspects of its epidemiology, such as its infectivity and the predisposing causes. Finally, there is a section entitled "The authors' conclusions." The first eight pages of this could have been more appropriately called "the authors' summary." In the last page and a half they give their judgment; this constitutes the "meat" of the whole monograph and we suggest that the busy practitioner who is interested in the subject should confine himself to this page and a half. The monograph also contains an excellent bibliography and 7 beautifully reproduced plates of photographs of streptococcal colonies.

Monographs II and III are short; they are historical reviews of researches on the rôle of streptococci in chorea, and erythema nodosum, respectively. Where-

as opinions are almost unanimous that chorea is a rheumatic manifestation, there is a feeble opposition to the theory of the association of erythema nodosum and rheumatic fever. We notice that Symes's monograph on the former condition does not appear in the list of references.

Part I of the volume is concluded with monograph IV, an historical survey of researches on the rôle of streptococci in carditis. The monograph is the largest of the four as we would expect it to be. Carditis, with its various aspects, subacute, acute simple and malignant endocarditis, myocarditis and pericarditis, is probably the most important disease of temperature climates.

The literature on the subject must be enormous and the authors have probably had considerable difficulty in separating the wheat from the tares. They give a useful summary at the end of the monograph.

The second part of the volume commences with a very short monograph (V) on suppurative arthritis, acute and subacute. In this condition streptococci play a more important part than do all other organisms put together; a plea is made for more accurate information regarding the type of organism present in this condition with the object of improving the treatment. Monograph VI is a far larger and more ambitious one and in it the editors have attempted to give an historical survey of the rôle of the streptococci in chronic arthritis. They first attempt to classify chronic arthritis and immediately encounter chaos. The main difficulty appears to be in distinguishing, and respectively defining, rheumatoid and osteo-arthritis; different writers appear to give diagonally opposite definitions for these two conditions. This section contains some excellent plates of streptococcal colonies, of histological sections, and of skiagrams to the joints of experimentally affected rabbits. The last monograph in the volume is an essay, rather than a review, of Rosenow's hypothesis of "elective localization" by H. Warren Crew. The term "elective localization" is not a very specific one and would have an entirely different meaning if used by Besredka, for example. By it Rosenow means the quality on the part of a micro-organism, a streptococcus, for example, of being able to acquire a specific affinity for certain tissues.

These *Annals* are reviewed regularly in the *Gazette* so that it becomes unnecessary to expatiate on the excellence of their "get-up"; as books they would add grace to the library of any bibliophile.

L. E. N.

Annual Report.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF BIHAR AND ORISSA, FOR THE YEAR 1928. BY LIEUT.-COL. J. A. S. PHILLIPS, D.P.H., I.M.S., OFFG. DIRECTOR OF PUBLIC HEALTH, BIHAR AND ORISSA, PATNA, 1929, SUPDT., GOVT. PRINTING, B. & O. PRICE Rs. 3.

THE estimated population of the two provinces for 1928 was 34,004,546, upon which figure the statistics in Col. Phillips' report are based. The birth rate was high, 38.3 per mille as compared with a previous ten years' average of 37.2; the general birth rate in towns, 25.8, being considerably less than that in the rural districts, 38.7. The death rate was low, 25.3 per mille as compared with a rate of 31.5 for the previous ten years. Accordingly the year 1928 was in general a healthy one for the two provinces. The chief epidemic of the year was one of cholera, which broke out from June to August in the Puri district, as a result of infection imported from the Rath Jatra festival. Infant mortality was 131.8 as compared with a figure of 133.4 in 1927.

The accuracy of 21,538 vital occurrences was investigated, with the result that 418 omissions were detected, 306 prosecutions instituted, and 216 convictions obtained. Most municipalities, however, have dispensed with the services of their health officers, owing to the withdrawal of the Government contribution towards the pay of these officers, and the checking of vital statistics has deteriorated in consequence. In the towns statistics of births and deaths are furnished by the police and not by the municipalities. Experiments were made during the year by the simultaneous collection of statistics, both by the police and by the municipal commissioners, in Patna and Ranchi to enable Government to consider whether municipalities could without loss of efficiency be compelled to provide for the registration of births and deaths. It is as yet too early to come to any conclusion on this matter.

The covering Government resolution to the report records that maternity and child-welfare work has made no headway amongst municipalities. "Efforts in this direction are at present confined to the work done by two maternity supervisors appointed and paid for by Government in Patna and Cuttack, and to the work of an unofficial provincial maternity and child-welfare society which was registered during the year under the presidency of Lady Stephenson, and which has organized and helped to finance such work in these two towns.

Turning to the chief diseases during the year, *cholera* was important, with an incidence of 2.2 per mille as against a general ten years average of 1.8. Puri, Motihari, Darbhanga, and Barh all recorded high mortality from this disease. By April almost all districts in the province were infected, the Puri epidemic commenced with the Rath Jatra festival and spread to several other areas, whilst the disease did not subside generally until November. Apart from the usual reserve of ten special assistant-surgeons on anti-cholera duty, 20 additional epidemic doctors were employed during the year, whilst 105 vaccinators were also engaged on special anti-cholera duty. The use of kaolin in treatment is favoured by the reports of civil surgeons, whilst 241,703 doses of cholera vaccine were issued, as against 38,566 in the previous year. Inoculation is steadily making headway in the province and pilgrims at the different festivals come forward readily for inoculation and even persuade others to do so. At Puri the installation of a piped water supply is a very urgent need, and a detailed scheme for this is under consideration.

Smallpox was unimportant, a mortality rate of 0.4 as compared with one of 1.0 in the previous year. On the other hand, Col. Phillips reports that this sense of security is a very false one, and conditions are rapidly becoming very bad; only 328 per 1,000 children are vaccinated, and in the rural areas the introduction of compulsory vaccination is urged. "The vaccination state of the province cannot be regarded as satisfactory" writes Col. Phillips. "When a severe epidemic prevails the number of operations increases, but when the disease is not very prevalent, the number falls off. This state of affairs will continue until vaccination is made compulsory." At Hazaribagh the Civil Surgeon devoted a great deal of his time to this special matter, with great improvement in results, and in Patna, the District Board paid special attention to it. Government considered the feasibility of extending the provisions of sections 92 to 96 of the Local Self-Government Act, relating to vaccination, to district boards which employ qualified health officers, and at the close of the year correspondence was going on in this connection.

The death rate from *fevers* was 16.6, as compared with a general return of 21.8 for the ten previous years. Plague remained stationary during the year, and there was a very marked increase in the sale of quinine,—from 398 lbs. in 1927 to 529 lbs. in 1928. The free issue of quinine tablets to school children has been extended, and this measure appears to be

rapidly gaining in popularity. *Dysentery and diarrhoea* appear to be especially prevalent in the Orissa division, which reported 13,504 out of the total of 17,439 deaths which occurred in Bihar and Orissa during the year from these diseases.

Page 11 of the report gives two very interesting tables; the first shows that in municipal towns the proportion of total expenditure on sanitary measures to total income is 35.4, whereas for district boards the corresponding figure is 4.3. In Bihar and Orissa, as almost everywhere else in India, the development of public health is checked by acute financial stringency. "Government explained last year that they were unable to give financial assistance to any more district boards than at present for financing public health staffs," runs the covering Government resolution. "The working of these organizations in the various districts in which they have been started was inspected by the Public Health Department during the year, and the impressions obtained on their work were, on the whole, encouraging." A conference was held at Ranchi during the year to discuss improvement in the arrangements for medical inspection in schools. The introduction of a piped water supply for the Sonopore mela deserves special mention, as this fair is attended by thousands of pilgrims from other provinces in India.

The general position with regard to municipalities is very unsatisfactory. "Owing to the high prices still prevailing, and to the considerable increase in the wages of the staff, municipalities have been finding an increasing difficulty in maintaining the efficiency of their administration and equipment," writes Col. Phillips. "It is necessary to face a permanent increase in expenditure if municipal administration and conservancy are to be maintained even at the low standard previously attained. This means that their revenues must be increased, and this is one of the problems with which municipal and district boards are now faced, and one which they are reluctant to pursue. . . . The employment of suitably qualified health officers in all the large municipal towns is very desirable. Sanitary inspectors and health inspectors, however hard working, have neither the experience nor the training to enable them to replace health officers, and when an epidemic disease breaks out in the town, they seem to be both powerless and incapable of checking its spread." Epidemic doctors are essentially recruited for work in rural areas, and municipalities ought to be able to deal with their own problems without calling upon the Public Health Department for assistance in towns. And when economy is the order of the day, the first appointment to be scrapped is that of the district health officer, with the result that inefficiency sets in and public health deteriorates.

The propaganda work carried out during the year was very strenuous; "this work is appreciated and serves a very useful purpose in spreading knowledge," writes Col. Phillips. The Jharia Mines Board of Health continued to carry out excellent work throughout the year. In the Public Health Laboratory 1,250 examinations were carried out: 32.7 per cent. of samples of ghee, 74.2 per cent. of mustard oil, and 66.7 per cent. of milk samples were found to be adulterated,—figures which are unfortunately only too characteristic of Indian conditions. Legal action was taken during the year to enforce a standard for tea.

The report also includes the annual vaccination report for Bihar and Orissa for the year 1928-29. There are three vaccination circles in the province, and a total of 1,202,342 vaccinations was carried out. Col. Phillips records that more than half the total number of vaccination of "infants" is now carried out on children more than one year of age. There is very considerable popular prejudice, not against vaccination itself, but against the vaccination of young infants. The Vaccine Depot at Namkum continued to work very satisfactorily during the year. The cost per successful vaccination was Rs. 0-2-6.

Correspondence.

NOTES ON *ULCUS TROPICUM* IN THE JHARIA COALFIELDS IN 1922.

To the Editor, "THE INDIAN MEDICAL GAZETTE."

SIR,—Noting in your comment on Dr. Doshi's letter in the January 1930 issue of the *Gazette* that you had found the infection among the grass cutters of the Cavalry Regiments in the U. P. in 1909—11, I was struck by your finding as compared with mine in the

few notes I made upon the disease in late October 1922. The statistics are from four fairly large collieries which were then under my charge, and, although they differ somewhat in compilation, they curiously all make reference to the grass in the notes. The description of the ulcer and the treatment thereof have been omitted, they tally exactly with present day observations, with perhaps some difference in technique of treatment, but, it was then largely a matter of opinion and experiment as to the way in which the period of inefficiency of the sufferer could be shortened; all however are agreed in the main.

Kustore Colliery (the Raneejunge Coal Association Ltd.).

Year.	No. of Cases.	Date of Appearance.	Date of Total Disappearance.
1919	120	7th June	6th December.
1920	104	27th June	30th November.
1921	46	3rd September	26th December.
1922	44	22nd July	Up to the 31st October and still continuing.

Note 1.—Site of ulcer nearly always on the anterior aspect of the leg below the knee joint, most often on the ankle and dorsum of foot. May be single or multiple. Attacks mostly confined to adult males, less common in females, and rare in children. Two cases however were noted on the arm during these years.

Note 2.—Occurrence generally from the beginning of

the rainy season or certainly when the grass becomes long and "spear grass" abundant. Found in Punjabi coolies, Beidars, and Bilaspuri miners.

Note 3.—Treatment if taken in hand early generally lasted from 12—18 days. If much erosion had taken place and there was much oedema present, treatment was considerably lengthened.

Jamadoba Colliery (Messrs. Tata Iron and Steel Co.).

Year.	No. of Cases.	Date of Appearance.	Date of Total Disappearance.
1919	109	July	November.
1920	169	July	December.
1921	98	June	December.
1922	41	July	Up to October 31st and then still occurring.

Note 1.—Site of ulcer always below the knee and mostly found adjacent to the ankle joint and on the dorsum of the foot. There was at times much oedema below the ulcer level.

Note 2.—The figures for 1919-1920 should not be recorded as being all tropical ulcers, but undoubtedly the majority of them were so owing to the seasonal

occurrence. The percentage of persons afflicted was much higher in the case of adult males. In 1920 only 2 children were affected and none in the other years under question.

Note 3.—From the records, it would appear that the disease reaches its height concomitant with the height and ripeness of the grass, and, that Beidars and others who work on the surface are more often affected.

Sigua Colliery (Messrs. Tata Iron & Steel Co.)

Year.	Total.	Appearance of 1st ulcer.	Date of total disappearance.
1919 ..	146 (including 4 females and 1 child)	July	December.
1920 ..	82 (including 6 females and 4 children)	June (late)	January 1921.
1921 ..	52 (including 9 females and 2 children)	July	December.
1922 ..	112 (including 6 females and 2 children)	June (late)	Up to October and still continuing.

Note 1.—The disease was noted on no other part of the body except the leg below the knee.

Note 2.—The disease is generally found in the months where the grass is highest and rankest, and has been most commonly found amongst the male earth cutters.

Malkera Choitidih Colliery (Messrs. Tata Iron & Steel Co.)

Year.	Number of ulcers.	Appearance.	Disappearance.	Length of period of inefficiency.
1919 ..	75 (females 5, children nil)	July	January 1920	12 to 16 days.
1920 ..	55 (females 4, children nil)	July	December	10 to 16 days.
1921 ..	80 (females 3, children 1)	August	December	10 to 15 days.
1922 ..	91 (females 5, children 2)	July	October 21st and still continuing.	10 to 15 days.

Note 1.—The ulcer is generally found on the lower one-third of the leg, more often on the anterior than on the posterior aspect. Mostly confined to the ankle and dorsum of the foot. May be single or multiple.

Note 2.—The percentage of affliction is found to be strikingly higher in adult males than in females, children being rarely afflicted. The age incidence varies from 20 to 45, and it is noted to be rare among elderly people.

Note 3.—Mostly seen amongst the poorer classes, but also found amongst the Punjabi coolies, Bilaspuri miners,

and surface coolies. A single instance in 1921 occurred in a Babu's family.

Note 4.—It may be of some interest to note that the ulcers are more prevalent at the end of the rainy season when the grass is long and in the seed-bearing stage.

You will thus note how strikingly the grass is blamed throughout. The rough notes were compiled by my assistants, who were not in communication with each other and were "boiled down" for my report to the Managing Agents. They all appear to have associated this element as a possible factor in the causation of the

ulcer, and, curiously enough, after a quiescent period the ulcers reappeared in great numbers in 1929, concomitant with a heavy monsoon and a consequent luxurious crop of grass!—Yours, etc.,

FRANK T. SIMPSON,
Chief Medical Officer,
Messrs. Kilburn & Co.'s Collieries.

KUSTORE,
P. O. KUSUNDU, E. I. Ry.,
MANNIUM DISTRICT,
30th January, 1930.

ULCUS TROPICUM IN KANARA DISTRICT.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I was much interested in the two accounts in the *Gazette* for December, 1929, and January, 1930, of a special kind of ulcer ("Naga sore") on the leg encountered by the writers in Gwalior and Rajputana respectively. From the authors' description of the sore, its site, its mode of onset, its resistance to anti-syphilitic measures, its relationship to economic conditions, and its common association with an enlarged spleen, I have no hesitation in identifying it with a certain variety of ulcer which occurs in South Kanara district, and runs an exactly similar course from beginning to end. The first few cases that I encountered I attributed to a possible syphilitic manifestation, but I soon found out my mistake. I then thought of ankylostomiasis, but was shortly able to rule that out. Some 80 per cent. of these cases show definite splenic enlargement, and many of them a well established condition of malarial cachexia.

Being in a remote and poorly equipped dispensary, I have had to rely on clinical experience only, and, by way of treatment, have so far hit upon no remedy which can be said to be truly specific. After trial of a variety of antiseptic dressings, I now use simple dressings with 1:2,000 hydrarg. perchloride lotion. Anti-syphilitic remedies are of no value in checking the disease. Internally I administer potassium iodide or triple sulphates as tonic alternatives. Daily changes of dressings are insisted on, but in spite of all care, the condition runs a prolonged and tiresome course towards recovery.

There is no possibility of guinea-worm infection in this part of the country.

I should be glad if Dr. Doshi would inform your readers of the details of "Dr. Hugh Smith's method" of treating these ulcers.—Yours, etc.,

BYNDOOR, A. S. HEBBAR, L.M. & S.,
SOUTH KANARA DISTRICT. Medical Officer.

(Note.—The treatments suggested at various times by different writers for the condition are legion. Intravenous injections of antimony preparations—often so useful in venereal granuloma—appear to be useless. Daily dressing with gauze soaked in hypertonic saline has its advocates; also eusol. Surface cauterisation of the entire ulcer—if not too large—with pure carbolic acid, immediately followed by neutralization with alcohol, has been advocated by some; but such a line of treatment might set up a risk of carbolic acid poisoning. Stitt mentions that Castellani advocates a preliminary cleaning with hydrogen peroxide, followed by a 5 to 10 per cent. protargol ointment. He also states that "an 8 per cent. scarlet red ointment should be tried on these sores when treatment with ordinary applications fails."

(Dr. Hugh Smith's treatment referred to by Dr. Hebbbar, is a method of prophylaxis (*Indian Med. Gaz.*, April 1929, p. 239). Each coolie, on returning from plucking leaf, is made to walk through a trough from 20 to 60 feet long, divided into two compartments: the first containing clean water, and the second a phenyl solution of sufficient depth to cover the lower third of the leg; the object being that the legs shall be cleansed in the first compartment, and disinfected in the second.—EDITOR, I. M. G.)

TANNIC ACID IN THE TREATMENT OF BURNS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—During the past few years, tannic acid has come into considerable vogue for the treatment of burns. As House Surgeon in the Sir J. J. Hospital in Bombay in 1927-28 I had to treat many cases of burns, but was unsuccessful with tannic acid. I asked my chief, Mr. S. R. Moolgavkar, F.R.C.S., as to the reason for this, and he gave me the following advice: first wash the burnt part thoroughly with 1:1,000 hydrarg. perchloride lotion, and then apply the tannic acid lotion, which must be freshly prepared.

Since being posted to this district I have had three very severe cases of burns, and have applied the above treatment with very successful results. Details of the cases were as follows:—

Case 1.—Lachi, motor driver, aged about 20 years, admitted on 7th March, 1929, with burns due to lighted petrol. Both hands and both lower extremities were burnt, also the face. An injection of morphia was given immediately to control pain. The affected parts were well washed with hydrarg. perchloride lotion, and blisters snipped. A layer of lint soaked in 5 per cent. tannic acid solution was then applied, a layer of cotton wool over it, and then a bandage. An injection of anti-tetanic serum was given, and the usual measures taken to combat shock. Next day the entire burnt areas were covered by a black slough, and daily applications of the tannic acid dressing were continued. The sloughs separated leaving a healthy granulating surface. The parts were then treated with a 5 per cent. tannic acid ointment, and later with sterile boracic ointment. There was complete recovery with no contracture, and in 2½ months the patient was back at work.

Case 2.—Kalu, police constable, was admitted on the 11th July, 1929, with his whole leg up to the middle of the thigh burnt with gunpowder. The other foot was also partially burnt. The same treatment as above was applied, but in place of tannic acid lotion, 5 per cent. tannic acid ointment was used throughout. The patient made a complete recovery, without contracture.

Case 3.—A female patient, aged 13 years, admitted on 21st July, 1929, with extensive burns from below the breast to the lower part of the knees, as the result of her sari catching fire. The hands and forearms were also burnt, as well as the front of the abdomen. The treatment was the same as in Case 2, tannic acid ointment being used. Recovery was complete without any contracture.

I have seen cases of burns treated with tannic acid by means of a spray. In my opinion this method is costly, and the treatment with a 5 per cent. ointment is simpler. The chief advantage of the spray method is that there is no necessity to bandage the part. In applying the ointment I have never had any occasion to use a hypnotic, and the dressings do not stick to the part as with a tannic acid lotion.—Yours, etc.,

MALUM SINGH B. DOSHI, M.B., B.S., B.S.C.,
Chief Medical Officer.

DUNGARPUR,
RAJPUTANA,
22nd January, 1930.

"ARS OBSTETRICA."

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In your issue for January 1930, Licut.-Col. V. B. Green-Armytage has recorded his extensive clinical experience in regard to general obstetric practice under the above heading. A point in this connection which I may be permitted to mention relates to his class II variety of cases of albuminuria observed during pregnancy. The history of such a case is as follows:—

Mrs. J., aged 18, pregnant 8 months, was admitted to hospital in an almost unrecognisable state, owing to oedema all over the body. Examination of the urine showed a flocculent deposit of albumin. The pulse was

of high tension, and the onset of eclampsia threatened every moment. Milk diet, rest, and the usual treatment for albuminuria failed to relieve the condition after a week's treatment.

It occurred to me that dried liver extract has an almost marvellous value in several toxic states and in reducing high blood pressure, and I administered one day one tube (P. D. & Co.) extract, equal to $3\frac{1}{2}$ ozs. of fresh liver. On this line of treatment all traces of oedema disappeared within less than a week, and the quantity of albumin in the urine decreased, though albumin was still present in traces after delivery. Headache and visual symptoms disappeared, and the patient underwent a normal delivery.

This line of treatment appears to be worth a trial in cases of threatened eclampsia.—Yours, etc.,

V. S. UMACHIGI, L.M. & S.

GADAG,
14th February, 1930.

KURCHI EXTRACTS IN AMOEBIASIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In the *Indian Medical Gazette* of the February number Dr. Akhil Ranjan Mozumder, M.B., published an article on the use of "Kurchi bark in Dysentery." The results of Dr. Mozumder's analysis of the alkaloidal contents of our preparation and that of some of our competitors, whose specimens we have analysed, was, in our opinion, totally incorrect.

The alkaloidal contents of the Union Drug Co.'s Liquid Extract of Kurchi is 0.8 to 1 per cent., the percentage varying slightly; that this slight variation is unavoidable is a fact well known to all chemical experts.

I standardize the Union Drug Co.'s Liquid Extract of Kurchi in a special way, as I have found that the process of standardization generally followed is not only cumbersome, but most unreliable.

Before mentioning the names of different firms and characterizing their products as "extracts-below-standard," Dr. Mozumder ought, in our opinion, to have invited the chemists of the different firms to criticize the chemical portion of his report. He has informed me in a letter that he depended upon a friend, the chemist attached to a rival commercial concern, and was guided by him in the chemical portion of his research. The result has been that Dr. Mozumder was misled and a ridiculously incorrect and prejudiced report published.

Dr. Mozumder has made out a case in favour of standardized Liquid Extract of Kurchi by asserting that the particular brand he recommended can be offered in the market at Rs. 2 per lb., duty free. The privilege of getting alcoholic extracts duty free is restricted only to Government institutions, and to a few charitable dispensaries. But, what about the general public? They must certainly pay much more than Rs. 2 per lb., because the excise duty must be added to this price. But let us take the case of Rs. 2 per lb., which, in Dr. Mozumder's estimation of 1 per cent. alkaloidal contents, yields 4.5 grms. of total alkaloids. This means that the privileged consumers, who pay no duty, will have to buy 2.25 grms. of total alkaloids per rupee. Is this cheap as compared with Kurchi Bismuthous Iodide? We sell this alkaloidal salt, under the name of Kurchibine, to the Government institutions, District Boards and all charitable dispensaries at 3.5 grms. of alkaloids per rupee.

I leave it to you, Sir, to say which treatment is cheaper—Cols. Acton and Chopra's kurchi-bismuthous-iodide, or Dr. Mozumder's liquid extract of kurchi.

I beg to thank you for providing me with space to publish the real facts, which I can prove in any authoritative institution.—Yours, etc.,

B. N. GHOSH, M.Sc., & P.R.S.

(Cal.), B.Sc. (Lond.), F.C.S. (Lond.).

Union Drug Co., Ltd.

86, CLIVE STREET, CALCUTTA,
20th February, 1930.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Colonel W. H. C. Forster, M.B., I.M.S., Inspector-General of Civil Hospitals, Burma, is appointed to be Surgeon-General with the Government of Bombay, with effect from the 27th January 1930.

Lieutenant-Colonel T. F. Owens, I.M.S., Chemical Examiner to the Government of Burma, is appointed to officiate as Inspector-General of Civil Hospitals, Burma, in addition to his own duties with effect from the 13th January 1930 (afternoon) and until further orders.

On reversion from the cadre of Agency Surgeons under the Government of India in the Foreign and Political Department, the services of Major M. Fazluddin, O.B.E., I.M.S., were placed at the disposal of the Government of India in the Home Department, with effect from the 20th January 1930.

The services of Major M. A. Jafarey, I.M.S., are placed at the disposal of the Government of the United Provinces for employment in the Jails Department with effect from the forenoon of the 28th January 1930.

Major W. C. Spackman, M.B.B.S. (Lond.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), D.T.M. (Lond.), I.M.S., to officiate as Resident Medical Officer, St. George's Hospital, Bombay, until further orders.

The services of Major L. H. Khan, I.M.S., are placed permanently at the disposal of the Government of Central Provinces for employment in the Jails Department.

Major C. M. Plumpton, F.R.C.S.E., M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S., to officiate as Civil Surgeon, Sholapur.

Major A. H. Harty, M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S., Resident Medical Officer, St. George's Hospital, Bombay, to officiate as Civil Surgeon, Sukkur, *vice* Rao Bahadur P. T. Kothary, B.M.S., transferred.

Subject to His Majesty's approval, the undermentioned officers, whose appointment on probation was notified in the London Gazette dated the 12th October 1928 (*see* Army Department Notification No. 1547, dated the 17th November 1928), are confirmed in the following order, on passing the necessary courses of instruction:—

Captain F. R. W. K. Allen, M.B.

Lieutenant A. V. O'Brien, M.B.

Lieutenant S. T. Davies.

Lieutenant E. S. S. Lucas.

Lieutenant H. W. Farrell, M.B.

Lieutenant J. S. McMillan, M.B.

Lieutenant V. E. M. Lee.

Lieutenant M. R. Sinclair.

Lieutenant G. B. W. Fisher, M.B.

Lieutenant R. A. Paton.

Lieutenant G. F. Condon.

Lieutenant H. S. Smithwick, M.B.

Lieutenant D. Tennant.

The services of Captain D. P. Bhargava, M.B., F.R.C.S.E., I.M.S., are placed temporarily at the disposal of the Government of the United Provinces with effect from the date on which he assumes charge of the duties of Principal of the Medical School at Agra.

LEAVE.

Colonel W. V. Coppinger, C.I.E., D.S.O., M.D., F.R.C.S.I., Inspector-General of Civil Hospitals, Central Provinces, is granted leave on average pay for 3 months and 21 days combined with leave on half average pay for 3 months and 9 days with effect from the 10th March 1930.

In supersession of previous orders, Lieutenant-Colonel T. C. McCombie Young, M.D., D.P.H., I.M.S., an officer of the Medical Research Department on foreign service under the Indian Research Fund Association, is granted leave on average pay for 6 months and 13 days combined with leave on half average pay for 17 months and 17 days, with effect from the 5th May 1928. His services are replaced at the disposal of the Director-General, Indian Medical Service, with effect from the same date.

In supersession of previous orders, Lieutenant-Colonel N. M. Wilson, O.B.E., I.M.S., Civil Surgeon, Simla West, is granted leave on average pay for 3 months and 22 days with effect from the 7th November 1929, and his services are placed at the disposal of the Government of the Punjab, from the 1st March 1930.

In modification of previous orders, Major G. C. Maitra, I.M.S., Officiating Assistant Director, Central Research Institute, Kasauli, is granted leave on average pay for eight months with effect from the 1st September 1929.

In supersession of previous orders, Major L. K. Ledger, I.M.S., an Agency Surgeon, was granted leave on average pay for 2 months combined with study leave for 7 months and 7 days and in continuation leave on average pay for 5 months and 13 days, with effect from 23rd February 1928.

PROMOTIONS.

Colonel to be Major-General.

J. D. Graham, C.I.E., M.B. (Supernumerary) dated 11th December 1929.

Majors to be Lieutenant-Colonels.

F. J. Kolapore, E. G. Kennedy, M.B., J. V. Macdonald, M.C., M.B., H. A. H. Robson, M.B., C. G. Howlett, M.B.—Dated 29th January 1930.

C. Newton-Davis, M.C., M.B., R. C. Clifford, D.S.O., M.C., F.R.C.S.E., C. Newcomb, M.D., H. E. Shortt, M.B., T. A. Hughes, M.D., H. L. Batra, M.C., D. McN. Taylor, M.B., W. O. Walker, M.B.—Dated 30th January, 1930.

Captains to be Majors.

A. Ba 'Thaw, M.B., dated 15th January 1930.

A. K. Sahibzada, M.B., dated 30th January 1930.

Lieutenant to be Captain (Provisional).

W. J. L. Neal, dated 26th August 1929.

RETIREMENTS.

Lieutenant-Colonel W. G. Hamilton, I.M.S., from the 4th October 1929.

The King has approved the retirement from service of Lieutenant-Colonel H. A. Williams, D.S.O., M.B., I.M.S., from the 11th January 1930.

NOTES.

LONDON MEDICAL EXHIBITION.

HORTICULTURAL HALL, WESTMINSTER,
OCTOBER 14TH TO 18TH, 1929.

Notes on Burroughs Wellcome & Co.'s Exhibit.

SEVERAL products issued as a result of scientific research, and other preparations of topical interest were shown by Burroughs Wellcome & Co. An outstanding feature was the series of illuminated cabinets. In one was indicated the sources of eight typical medicaments of vegetable origin used in the production of well-known products of the firm. These consisted of hand-painted illustrations of the plants, the beauty of which would entitle them to attention on this score, apart from their professional interest. In a companion cabinet were shown novel illustrations of the sources of eight typical medicinal substances of animal origin together with "Tabloid" products prepared from them. The causative organisms of certain specific diseases were similarly shown as illuminated coloured photo-micrographs. Associated with these were products used in the diagnosis, prophylaxis and treatment of the diseases concerned.

Prominence was given to "Tabloid" Alkaline Compound, Effervescent, a therapeutic agent with a three-fold purpose. It may be used (1) as an antacid draught, (2) to correct hypo-alkalinity associated with gastric disturbance of various kinds, or (3) to restore the alkaline balance and assist re-mineralization in the condition now known as acidosis.

A coloured chart illustrated a test for the Vitamin B content of "Kepler" Malt Extract. "Kepler" Malt Extract is an important source of Vitamin B and "Kepler" Cod Liver Oil with Malt Extract presents Vitamins A, B and D in their natural form and association.

Burroughs Wellcome & Co., have issued a new, and, what is important, a really stable digitalis product—"Diginutin"—consisting of a solution of the total glucosides of digitalis leaves freed from inert vegetable matter. "Diginutin" may be used in place of the tincture.

"Tabloid" Brand Hypodermic Bulbocapnine Phosphate was shown as an adjunct to the treatment of certain phases of epidemic encephalitis. This alkaloid is derived from the root of *Corydalis cava*. In dealing with the disorders of behaviour in children, which frequently supervene in this condition, considerable success has attended the administration of bulbocapnine.

A mortality chart recorded the results of insulin treatment on 1,316 patients and indicated how case-fatality has decreased as a result of improved technique. A specimen of crystalline insulin from which Burroughs Wellcome & Co. insulin products are prepared was also available for examination.

THE BLOODLESS PHLEBOTOMIST.

THE Denver Chemical Manufacturing Co., New York, the manufacturers of the very well-known product Antiphlogistine, continue the publication of this well edited little journal, and have recently issued Vol. VII, No. 3. This contains an abstract from the work of Schaffer, which shows that the application of hot moist dressings in inflammatory conditions is productive of better results than the application of either dry heat or cold,—an article illustrated by microphotographs. Dr. S. J. Tchechulin of the Chemico-Pharmaceutical Institute of Moscow details experiments carried out with a view to resuscitating the severed head of a dog, and keeping it alive. The cardinal difficulty to be overcome in these experiments was not to supply an artificial heart and blood supply, but to give a blood supply containing oxygen in such form that the cerebral tissues could absorb it. This was found by using normal dog's blood, after treatment of the animal with Germanin (Bayer 205) to prevent coagulation. The severed dog's head, and the normal reflexes, were kept living for up to four hours.

The editorial deals with the need for local and topical treatment in inflammatory affections, whilst an interesting account is given of the Gastro-Photot apparatus. This is designed to take minute photographs of the interior of the stomach, which, when enlarged, can be studied for pathological changes; and it should largely do away with the necessity for exploratory laparotomies. A most quaint article is one by Robert Francheville on the planets and medicine, illustrated by delightful woodcuts; the author discusses from mediæval sources the influences of the planets on temperament and disease. We gather that the infant who is to be a doctor should choose to be born on a Wednesday, but he is liable to suffer from the gout, and will have three wives.

VITAMINE D.

THE history of the work on vitamine D is of considerable interest. At the outset of research on the vitamins, it was confused with vitamine A, since both are present together in fresh cod-liver oil, McCollum, however, identified it as a different and anti-rachitic principle by oxidising cod-liver oil, thereby destroying vitamine A, but yet being able to cure rickets with the product which remained.

About the same time Dr. Steenbock of Wisconsin University, discovered that foodstuffs could be endowed with anti-rachitic activity by means of radiation from mercury vapour and other ultra-violet ray lamps—a discovery of the utmost importance. It was found that irradiated cholesterol would cure rickets, but later that highly purified cholesterol was unaffected by irradiation. The suggestion was therefore made that an impurity associated with cholesterol—probably another sterol—was the precursor of vitamine D. In 1926-27 Rosenheim and Webster in London, Hess in New York, and Windhaus at Gottingen, almost simultaneously identified ergosterol as the pro-vitamine substance.

The preparation of vitamine D by the irradiation of ergosterol is thus the outcome of Steenbock's researches.

and products prepared by and marked "Steenbock Process" are therefore reliable. Such a step is now not infrequently taken by research workers who desire that their results shall not be unscrupulously exploited, and that only reliable products shall be placed on the market. The period of radiation of ergosterol is important, for if under-irradiated it is worthless, and if over-irradiated the vitamin D is destroyed. Further, the product has to be biologically standardised after preparation.

The agents in India for the Steenbock product are Messrs. H. J. Foster & Co., 13, Government Place, East, Calcutta, who will be glad to supply information. Vitamin D, in the form of irradiated ergosterol, has a very wide range of application, being used in rickets, tuberclosis, osteomalacia, pregnancy and lactation, corneal ulcer, and defective dentition. We trust that investigations will be carried out into the keeping properties of this, and other vitamin products, under tropical conditions—a point to which attention has been called by contributors to our columns.

SICCOPAN.

THIS is a new hæmoglobin preparation, manufactured by the original makers of dried hæmoglobin, the Sisco Chemical Works, Berlin. It is stated that it consists of a pure hæmoglobin in powder form, with the addition of lecithin albumin, calcium lactate, and silicic acid. A report by Dr. Fritz Stern of the Berlin-Lankwitz Hospital speaks highly of results with it. The product was found to be completely soluble in water, readily assimilated, and only excreted in inconsiderable amounts; only traces could be detected in the feces after its administration. Patients to whom it was administered showed a fairly constant increase of from 15 to 20 per cent. in the hæmoglobin content, and an increase in weight. The preparation appears to be especially suitable for anæmic and convalescent patients.

The British agents, Messrs. Coates & Cooper, 41, Great Tower Street, London, E. C. 3, follow strictly ethical lines in bringing forward notice of new preparations to the medical profession only. The claims made for Sisco are restrained and not exaggerated. For both reasons we consider that the new preparation may be of interest to the medical profession.

MARMITE.

MARMITE is so well known a product, and with so well established a reputation, that we need only draw our readers' attention to it briefly. Essentially it is a yeast preparation designed to supply the vitamin B in which modern dietaries are usually very deficient, and which cannot be stored up in the body metabolism. One of the most striking instances of its value was its use during the Great War. In January 1916 beriberi broke out among the troops in the Gallipoli peninsula, and Dr. C. J. Martin, F.R.S., recommended the addition of yeast to the soldier's daily ration. Lieut.-Col. Monkton Copeman, then in charge of the Hygiene Department of the Royal Army Medical College, however showed that Marmite possessed the advantage over crude yeast of remaining practically unchanged when exposed to the air. Miss Chick and Miss Hume, in their well known work on the distribution of anti-beriberi vitamins, also reported very favourably on the product. Accordingly two preparations were manufactured; Marmite cubes or tablets, and Marmite S₂, which consisted of two-thirds Marmite and one-third concentrated essence of onion, carrot, aromatic herbs, and bacon extract. In the latter preparation cotton seed oil was later substituted for bacon fat in order that the preparation could be issued to Indian troops. Supplies were sent to Gallipoli, and monthly supplies, which finally totalled 10,000 lbs. a month to Basra for the Indian Expeditionary Force in Mesopotamia. The preparation was also used extensively in the parcels of food sent to British prisoners of war in Germany and Austria. The result was that beriberi was abolished (Sir David Bruce, inaugural address at the annual meeting of the British Association for the Advancement of Science at Toronto, 1924).

All experiments carried out with the preparation on experimental animals, chiefly rats and pigeons, have proved its value, and that it retains a considerable supply of vitamin B. It can be added to soups or gravies, or taken in the form of sandwiches, added to poached eggs, or to custard. The uses of this preparation are very numerous; it is of value in promoting growth in marasmic and weakly children; in promoting fat assimilation in constipation, defective digestion, and diabetes; in inducing leucocytosis in all conditions of chronic sepsis; and of special value in the dietary of nursing mothers.

The manufacturers of Marmite—the Marmite Food Extract Co., Ltd., Mincing Lane House, 59, Eastcheap, London, E. C. 3—are studiously restrained in their claims for the preparation, and strictly ethical in their advertising. But the preparation has now so well known and so established a reputation that it needs no further recommendation on our part. A detailed account of its use during the war will be found in the *Official History of the War, Vol. II, Medical Services, Hygiene of the War*, Chapter III, pp. 83–86, by Major-General Sir W. MacPherson, Col. Sir W. H. Horrocks, and Major-General W. W. O. Beveridge.

THE SOLLUX LAMP.

THE use of luminous heat rays for the treatment of inflammatory processes is one of the most interesting and important of the recent advances in electro-therapeutics. Practically speaking, the method is an adaptation of Bier's method of inducing local hyperæmia, but differs from the latter in that applications can be accurately controlled, and that the application is far more convenient and pleasant than with Bier's method.

In this connection the British Hanovia Quartz Lamp Co., Slough, Great Britain, have produced their Sollux Lamp, and will send an illustrated brochure with regard to it on application. This apparatus is designed, (a) as a stand model, and (b) as a suspension model. Several different types of localizers are illustrated for use with the lamp, and for application to different parts of the body. Essentially what the treatment aims at is to relieve pain in all cases of localized inflammation, to cause subsidence of the inflammatory process, and to lead to the early clearing up of the morbid condition. It is claimed that the lamp is of special value in dental and oto-laryngological work; of value in localized sepsis, rheumatism, neuralgias, gont, and lumbago; and in all conditions where it is desired to produce a localized hyperæmia.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers, relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 54, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India, Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

THE MATERNITY CONDITIONS OF WOMEN MILL-WORKERS IN INDIA.

By MARGARET I. BALFOUR, C.B.E., M.B., C.M.,
and

SHAKUNTALA K. TALPADE, M.B., B.S.

(An Enquiry carried out under the auspices of the
Indian Research Fund Association, Haffkine Institute,
Bombay.)

THERE is little real information in India about the maternity conditions of women mill-workers. It is generally believed they are bad and that special action is needed, but unless we get more definite knowledge of the effect of maternity on women workers there is danger that the remedies may prove wide of the mark and unsuited to the needs of the women.

Amelioration of the conditions of women mill-workers is not of importance for sentimental reasons only. One of the difficulties connected with labour in India is the shifting nature of the industrial population. Men come from their villages leaving their wives behind and as soon as they have saved a little money they are eager to go back to enjoy the amenities of home life. They are the more ready to strike because they have a village home to return to. When the worker brings his wife to the city and perhaps his children too, his work and its steady continuance becomes of much greater importance to him. If his wife also works in the mill, he has a larger stake in its prosperity. Hence thought and organization regarding the employment of women will do much, not only to improve their own work, but to render the employment of men more dependable and stable.

The special disability under which women suffer with regard to work is maternity. How is that affected by work? Is the mother adversely affected, and is the child adversely affected? And if so, can anything be done to remedy matters without shutting the woman off from a source of livelihood which is well within her powers at ordinary times?

Interest in this question was aroused in India after the first International Labour Conference held at Washington in 1919, (1) where Articles were passed in the Draft Convention, providing for the safeguarding of maternity among women workers. It was required that each expectant mother should have six weeks rest before and six weeks after confinement, and that she should be paid benefits sufficient for the full and healthy maintenance of herself and her child. At this Conference the special circumstances of India were recognized and it was not expected that she should adopt these articles at once.

But she was asked to look carefully into the matter and find out what could be done to put the maternity conditions of women workers on a proper footing. The Government of India thereafter addressed Local Governments asking how far it would be possible to introduce maternity benefits or at least to carry out an enquiry as to the need of them. The replies from Local Governments were not encouraging. The situation was the same then as now. The Local Governments did not wish to undertake the expense, either of an industrial maternity scheme, or of an enquiry. The employers of labour were in the same position—while it was felt that the workers were at once too poorly paid and too ignorant regarding their own welfare to be willing to contribute the small sum necessary for an insurance scheme. In the year 1921 the Secretary to the Government of India in the Department of Industries and Labour, Mr. A. C. Chatterjee, called a meeting at Simla of various persons, representing chiefly medical and social organizations, to discuss the question and to ask for suggestions. As a result of that meeting an offer was made by the Countess of Dufferin's Fund to give the services of two medical women for an enquiry on the maternity conditions of women industrial workers in two different parts of India. This offer was accepted by the Government of India and by the two Local Governments concerned, Bengal and Bombay, and in the year 1921-22 enquiries were carried out in Bengal by Dr. Dagmar Curjel and in Bombay City by Dr. Florence Barnes.

These medical women were lent from the Women's Medical Service for one year only. The object was "to determine the influence which industrial work might exert on the Indian woman worker, especially during the child-bearing age and on the well-being of her child." The enquiry in Bengal included the jute, cotton, tea and coal industries, and in Bombay the cotton industry.

Both reports [(2) and (3)] give a great deal of valuable information as to the conditions under which women work in India and as to their domestic and social relations. They make it plain that childbirth is looked upon as something quite outside the province of the employers. Medical relief for ordinary ailments may be provided by means of mill doctors and mill dispensaries but no arrangements are made for childbirth. An expectant mother disappears when her time is near and reappears when she wishes. She may, or may not, be taken on again. The factory has no information to give regarding her confinement, her child, or the frequency of her pregnancies. Hence these medical women's reports could only give general information such as the facts that many women were confined in their own *chawls* by *daïs*, while others returned to their village homes for the occasion. They had no time, nor had they any opportunity to follow the women through their

confinements and to note the immediate results to mother and child.

Following the issue of these reports and in consequence of them, welfare centres were started in certain mills in Bengal, while in Bombay a medical woman was appointed with the status of factory inspector with the special task of organizing welfare work among women. There are now crèches in connection with thirteen mills, while maternity benefits have been given for some years by two groups of mills in Bombay City.

In the year 1925, having received a grant from the Indian Research Fund Association, Simla, for the investigation of the causes of maternity mortality in childbirth in India, we began work in Bombay and included the maternity conditions of mill-workers with those of other classes. Our intention in doing so was to supply what we felt was a lack in the earlier reports, and to collect evidence as to the actual effect of work on pregnancy as it occurs in women living under the conditions of the Bombay mill-workers. For this purpose it was necessary to keep records of the deliveries of a number of women workers, of a control series which was best found in women of the mill-working community living under the same social conditions but not employed in the mills, and a second series of controls, women of a rather better social position delivered in other hospitals in Bombay.

The facilities for such an investigation which did not exist before had been provided by the opening in 1923 by Sir Ness Wadia of a maternity home in the mill area, specially intended for mill-workers. In 1927 this home was moved to the fine new building of the Nowrasjee Wadia Hospital at Parel, built and partly endowed by Sir Ness Wadia and his brother Mr. C. N. Wadia. By the kind permission of Dr. M. V. Mehta, the Principal Medical Officer, we have been permitted to attend the hospital and note the conditions of the mill-workers confined there. The number of the mill-working class who attend hospital are even now small, as they still prefer delivery in their *chawls* or villages, and for this reason we have kept the enquiry open until May 1929, during which time we investigated 576 cases of labour among women of the mill-working class. Of these 282 were women actually working in the mills, and 294 were the wives of male mill-workers living under the same social conditions as the first, but not employed in the mill.

With the kind permission of the Millowners Association and of the managers concerned, we visited a number of mills and saw the conditions under which the women worked. We were accompanied by Dr. T. J. Cama, who, as already stated, holds a special post as Factory Inspector under the Government of Bombay and who showed us several of the mill crèches and of the dispensaries officered by medical women

(4 in number). She also took us to see several of the most insanitary *chawls* available, for which we were duly grateful.

During the same period we have been watching the maternity conditions of women of other classes in the City, especially in the Cama and Allbless Hospital, to the successive Superintendents of which we are grateful for the facilities so kindly given. In many cases we watched the after progress of our patients by visiting them in their homes, either *chawls* or better class houses, and so gained much knowledge of the conditions under which the different communities live. We have also carried out some observations on the diet of the people.

Before entering on the special question of maternity conditions it may be well to make some remarks on the habits and ways of living of the women of the mill-working class.

(1) The *housing* is poor. The people live in *chawls* or large tenement houses, which are usually built with a long central passage from which rooms about 12 by 15 feet in area open on each side. The room may be occupied by one family, or, in order to save money on the rent, several families may share it. A case is described by Barnes (3) where 36 persons inhabited a room 12 by 15 feet. This is an extreme instance of overcrowding, but it is common to find 6 or 10 people inhabiting such a room, in which the women will also have their deliveries.

One of us personally investigated the homes of 20 women of the mill-working class and found that the average space at night per head was 240 cubic feet. A similar investigation was made of the homes of 70 women of the poorer non-industrial class and it was found that the cubic space at night worked out to 534 per head.

The rooms usually have a window opening on the street but the only other air space, the door, opens into the passage, not into the outer air. The one window may not open directly to the air, but into a verandah where the family cooking is done, so that the air which enters is contaminated with smoke. The window may be blocked by neighbouring buildings, so making the room close and dark. The housing question is improving and many new *chawls* are being built in the open areas to the north of the city. These are not yet fully occupied, but as they become more popular they should do good, especially if overcrowding within them can be prevented.

(2) *Sanitation* is water borne and there is a good drinking supply. In the newer *chawls* there is a tap in each passage and a room for bathing. Each *chawl* has a superintendent responsible to the owner for general order and cleanliness. In spite of this most *chawls* are dirty, the passages littered with rubbish and swarming with unwashed children. The rooms are often dirty and disorderly, but here and

The diet of the mill-workers consisted chiefly of *bajri* bread, rice, vegetables (potatoes, onions, pumpkin, *brinjal*), and some *dal* or gram with

occasional small quantities of fish or mutton. Milk and *ghi* were almost never taken, eggs never, and very little vegetable oil. Fruit was never taken—this may be different at the time when mangoes are cheap.

In the non-industrial classes more rice was taken and less *bajri*. If wheat was taken it was in small quantity. Milk and *ghi* were often taken and fairly large quantities of vegetable oil. Fruit was sometimes included in the diet, and either meat or fish was taken most days by non-vegetarians. White bread was sometimes taken and especially by Christians. Vegetables sometimes included tomatoes or greens, though in small quantity.

Table I shows the average diet of the 20 mill-workers as compared with the average diet of 70 of the poor non-industrial class. Included in the table is the blood count, the cubic space per head and the family income. It will be seen that the mill-workers were better caloric and had a higher proportion of carbohydrate than the hospital controls. Their diet was extraordinarily deficient in fat, and especially in animal fat, also animal protein.

The difference in the diets was probably due to the fact that the mill-workers, although the poorest community, were bound to have a good supply of calories or they could not have got through their work. Hence they bought the cheapest and most filling foods. They drew their vitamin A from *bajri* and *dal* of which they took a fair amount. Their vitamin B was from the same source and from the vegetables (which were not containers of vitamin A). Vitamin C was no doubt obtained to some extent from the vegetables, although these were cooked. There did not appear to be any source of vitamin D except the small bits of mutton rarely taken, but the women went out freely and no doubt sat in the sun and got a supply of vitamin D through the skin.

The vitamin A supply of the non-industrial class largely depended on milk and milk products, which, in Bombay at least, are doubtful containers. The mill-workers obtained their vitamin A supply from grain, which is a certain source.

Table I shows that when the vitamin A column was corrected to allow for the bad *ghi* the mill-workers had nearly as much vitamin A as the non-industrial class, while they had a slightly larger vitamin B intake.

These facts will be referred to later in connection with disease and mortality in child-birth.

(6) *Habits and work.*—Women of the industrial classes do not observe *purdah*. The women of Class B rise early as the men have to be at the mill by 7 a.m. They cook the food, then clean the cooking and eating vessels, do the family marketing and the family washing. Many carry their husband's dinner to the mill daily. Many take in boarders from among

the single men working, and cook their food and carry it to the mill. They have, of course, no servants, so they are forced into the open air each day and have fairly active lives.

Women of Class A work in the mills from 8 a.m. to 5-30 p.m. (sometimes longer) with an hour's interval at midday for food. They have the advantage of a walk to and from the mill, and sometimes a second walk at midday if they come home for their food. They spend their days in the big factory rooms, which are on the whole, clean, light and airy, at least as compared with most of the *chawls*. The joint income earned by themselves and their husbands should make better living possible and in some cases, no doubt, it does so, but the tendency of the men to gamble and drink too often leaves the family with nothing but the mother's wages for support. It is generally agreed that the women themselves never drink.

The women are employed chiefly in the winding and reeling departments. This is not heavy work. It entails standing before a frame, watching the yarn wind and removing and replacing it when finished. The attention must remain fixed on the bobbin throughout, as broken threads unnoticed spoil the yarn when it comes to weaving.

In some cases there is a mother-in-law or other female relative living with the family, who does the home cooking and housekeeping. In other cases the woman herself has to do it. This entails getting up at 5 or 5-30 a.m. to kindle the fire and cook the midday meal. At the midday interval she may come home to serve the food to husband and children. When work is finished in the evening she does her marketing and goes home to cook the evening meal. After it is eaten she has to do the cleaning up and various odd jobs about the house. Some women said they got up at 5-30 a.m. and did not get to bed till 10-30 p.m. working all the time. If there is a young baby and no one to leave it with save perhaps a little sister or a neighbour, it can be imagined how this must add to the woman's tasks and anxieties, and one cannot wonder that, not realizing the danger, she is so liable to dose it with opium. Out of 83 mills in Bombay City only 13 have crèches attached.

(7) *Age and caste.*—Of the mothers of Class A, 11 per cent. were below 20 years, 62 per cent. between 20 and 30 years, and 25 per cent. over 30 years. Only 2 were 15 or younger, the youngest being 14.

Of the mothers of Class B, 20 per cent. were below 20 years, 59 per cent. between 20 and 30 years and 20 per cent. over 30 years. Four were 15 or younger, the youngest being 14. In fact there were fewer very young mothers in Class A.

The great majority were Hindus, in Class A, all, except for 3 Christians and 3 Mahomedans; and in Class B all, except 7

Christians and 12 Mahomedans. This does not probably show the real proportions of these communities among the industrial classes, for Mahomedan women have a great objection to attending hospitals staffed by men (as is the case in the Nowrasjee Wadia Hospital) and as a matter of fact they went in small numbers to the Cama Hospital (staffed by women) and were not included in these figures.

The effect of work on childbirth.

1. *The mother.*—This question may first be studied by comparing the maternity conditions of industrial and non-industrial women.

carbohydrate and not fat, the content of which in the diet is extremely low. It has been shown McCarrison(6), Ederer(7), Harris and Moore(8) that the higher the fat content of the diet the greater the need for vitamin B in the diet, especially if the "A" content is low. It would seem as if the low fat intake and the relatively high vitamin B content of the diet placed the mill-workers in a relatively better position as regards diet than the non-industrial workers, whose diet, though more varied, richer in fats and better supplied with animal products, is yet not sufficiently rich in the essential vitamins to permit of the proper utilization of

TABLE II.
Labour cases seen in Bombay hospitals.

	Community. 1925—1929.	OSTEOMALACIA.		ECLAMPSIA.		ANÆMIA.		MATERNAL MORTALITY.
		Number.	Rate per 1,000.	Number.	Rate per 1,000.	Number.	Rate per 1,000.	Rate per 1,000 births.
Non-industrial classes.	Hindu, 2,066 cases.	6	2.9	8	3.8	83	40.1	16 per 1,000 births.
	Mahomedan, 842 cases.	32	38	14	16.6	79	93.8	
	Christian, 801 cases.	nil	nil	3	3.7	39	48.6	
Industrial classes.	Mill-workers, 576 cases.	1	1.7	1	1.7	6	10.5	1.7 per 1,000 births.

The table shows that there is a marked difference between the maternity conditions of the two classes, the incidence of disease connected with pregnancy being much less in the industrial class. The maternal mortality is also much lower, only 1.7 per 1,000, which would be low for any country. It is possible that some deaths may have taken place after the patients left hospital, since they were discharged on the 8th or 10th day, but the same may be said about the women of the non-industrial class. The maternal mortality for the city of Bombay for the years 1926, 1927, and 1928, as reported by the Health Officer was 13.9, 9, and 9 per 1,000 births respectively. "Mill-workers" as shown in Table II includes both actual workers and non-workers (the wives of the male mill-workers) but there was no marked difference between the two classes so far as maternal disease or mortality was concerned.

The low maternal mortality among the mill-workers is of course due to the low incidence of the toxæmias and other diseases of pregnancy in this class. This immunity is probably directly associated with both the diet and the mode of life of these workers. The diet is well caloric but the calories come very largely from

these elements. The more active and open air life of the mill-workers must also be conducive to better health.

2. *The child.*—The infant birth weight is lower in the industrial than in the non-industrial class and the question arises why should this be so if the maternal conditions are better? The answer no doubt is that the mill-working class has a diet almost devoid of fat. During the last month or two of foetal life the principal change in the foetus is the deposition of fat under the skin. It is possible that the almost complete lack of fat in the mother's diet associated with a low vitamin content may be directly related to this failure to deposit fat in the foetus.

In addition there is the effect of work. The numbers which we have investigated are not sufficiently large to enable us to give a definite pronouncement on this question, but so far as they go they tend to show that although the mother is not prejudicially affected by work, her child is smaller than those of the non-workers and her stillbirth rate is higher.

Our evidence is based on the following:—

1. A comparison of the infant birth weight and the stillbirth rate in

TABLE III.

Number of infants in different weight groups.

Group.	No. of cases.	3 TO 4 LBS.		4 TO 5 LBS.		5 TO 6 LBS.		6 TO 7 LBS.		7 TO 8 LBS.		8 TO 9 LBS.		9 TO 10 LBS.		Mean weight lbs.	Standard deviation.
		No.	%	No.	%	No.	%	No.	%	No.	%	No.	%	No.	%		
A. Mill-workers	223	6	2.6	37	16.5	93	41.7	66	29.5	20	8.9	1	0.4	5.502	0.932
B. Wives	236	2	0.8	27	11.4	80	33.9	95	40.2	31	13.1	1	0.4	5.813	0.861
C. Non-industrial	518	7	1.3	32	6.1	140	27	198	38.2	122	23.5	13	2.5	4	0.7	6.095	0.982

9.3% of Class A, 13.5% of Class B and 27% of Class C were over 7 lbs. at birth.

TABLE IV.

Number of infants in different weight groups.

Group.	No. of cases.	3 TO 4 LBS.		4 TO 5 LBS.		5 TO 6 LBS.		6 TO 7 LBS.		7 TO 8 LBS.		8 TO 9 LBS.		9 TO 10 LBS.		Mean weight lbs.	Standard deviation.
		No.	%	No.	%	No.	%	No.	%	No.	%	No.	%	No.	%		
(a) Mill-workers prior to strike.	134	4	2.9	27	20.1	57	42.5	39	28.8	8	5.9	1	0.7	5.377	0.897
(b) Mill-workers during and after strike.	89	2	2.2	10	11.2	36	40.4	27	30.3	12	13.4	0	0	5.713	0.9125

6.7% of Class (a) and 13.4% of Class (b) were over 7 lbs. in weight.

- A. Women mill-workers (223).
 B. Wives of male mill-workers, not themselves working (236).
 2. A comparison of the same facts in
 (a) Women mill-workers delivered between October 1925 and April 1928 (134). During this period work was being carried on regularly in the mills except for occasional short strikes.
 (b) Women mill-workers delivered between May 1928 and April 1929 (89). During this time there was a six months' general strike from April to November, when the women workers had an enforced rest.

Table III shows the numbers of infants in different weight groups of A, B and C. It will be seen that in nearly every weight group B takes a place between Classes A and C.

Table IV shows the same numbers with regard to (a) the mill-workers up to the commencement of the general strike and (b) the mill-workers after the commencement of the strike and for the 6 months following. It will be seen that (b) has a smaller percentage in the lower weight groups and a larger percentage in the higher weight groups.

Table V shows the differences and significances of differences of the mean weights of the infants in the groups studied. In each case the differences are significant.

class (hospital) remained round about 100 per 1,000 during this period, excepting the Mahomedan community where it was much higher.

An effort was made to check the condition of the foetus further by comparing the proportion which the foetal weight bore to the maternal weight. The maternal and infant weights were taken in a series of groups, Hindu, Mahomedan, Christian (all of the hospital class), also mill-workers and mill-workers' wives. In none of the groups was any significant difference found in the percentage of the foetal to the maternal weight, with the single exception of the mill-workers. In this group the proportion which the child's weight bore to the mother's weight was significantly less than in the other groups. It is possible that this, as well as the absolute lowering of the child's weight, is associated with the lack of fat in the mother's diet which is of such a degree as is never seen in any class in Britain. (9)

To sum up we find that—

1. The infants of the industrial class have a significantly lower birth weight than those of the non-industrial class.

2. The infants of the workers have a lower birth weight than those of the non-workers in the industrial class, and this is emphasized by the fact that during the strike year when work for a large part of the year was not possible the infant birth weight of the worker class approximated to that of the non-workers.

TABLE V.

Differences and significances of differences of mean percentage weights of infants in groups studied.

	Standard group.	Group compared.	Difference of means.	Significance.
1. a.	Non-industrial class	Industrial class ..	—0.439 *	6.3 †
b.	" "	Wives of mill-workers ..	—0.282	4.0
2. a.	Wives of mill-workers	All mill-workers ..	—0.311	3.75
b.	" "	Mill-workers before strike ..	—0.436	4.44
3.	Mill-workers after strike	" " " "	—0.336	2.70

* Difference of the means.

† Difference of means divided by square root of the sum of the squares of the errors of the two means.

$\frac{M_1 - M_2}{\sqrt{E_1^2 + E_2^2}}$ If result 3 or more difference is taken as definitely significant: if between 2 and 3 as probably significant.

With reference to stillbirth it was found that Class A (mill-workers before the strike) had a stillbirth rate of 178 per 1,000 births, while that of Class B for the same period was only 86 per 1,000 births. During and following the strike the stillbirth rate of Class A fell to 98 per 1,000 while that of Class B rose slightly to 114 per 1,000. The stillbirth rate of the non-industrial

3. The stillbirth rate of the non-workers in the industrial class approximated to that of the non-industrial class. That of the workers was much higher, but during the strike year came down to the same or an even lower level than the others.

4. In the mill-worker group alone the infant birth weight was a significantly lower percentage

of the mother's weight than was the case in the group of Hindus taken as standard.

It appears probable, that a part of the foetal disability is due to the fat-deficient diet, also that work, at least under the conditions it is carried on in Bombay, is prejudicial to the foetus. It is easy to understand that the fat deficiency may not be so serious if the mother has a comparatively easy life and plenty of time to rest, and it is also likely that the work might not affect the child prejudicially if the mother had a reserve of fat on which it could draw during the later months of pregnancy. It is possibly the combination of these two factors which reduces the infant weight and increases the tendency to stillbirth.

There is some evidence pointing to the fact that the infants of workers who have to do their housework and the infants of mothers who go on working until nearly full time, suffer more than the others in respect to the disabilities given above, but this is not sufficiently substantiated to dwell upon.

An endeavour was made to contrast infant and child mortality in the industrial and non-industrial classes by asking each woman the number of her past confinements and the number of her surviving children: 500 consecutive women delivered in the Cama Hospital were so questioned and their replies were compared with those received from the 571 women of the industrial class, delivered in the Nowrasjee Wadia Hospital: 62 per cent. of the non-industrial children survived as compared with 43 per cent. of the industrial children.

How can the conditions of women mill-workers be remedied in order to produce better conditions for the child?

In considering this question we should try and dissociate our minds as far as possible from the conclusions already reached in Europe on this question. Conditions in Europe and India are very different. Women workers in India have special difficulties to contend with which should not be forgotten in endeavours made to ameliorate their circumstances. (1) There is greater poverty and a diet lacking in nutritive power. Hence the people have little reserve of strength. Many of the women workers begin to feel exhausted before pregnancy is far advanced, and give up work on this account, at the 5th, 6th or 7th month. If the maternity benefit is given on condition that the woman remains at work until the end of the 8th month, many will continue working when physically unable and the result will be worse than before. (2) The principles of maternity and child welfare are not understood among the people. Fathers do not realize their responsibility to the unborn child, nor, perhaps, does the mother herself. Hence if two months' salary were given to her, it would too often be used for the benefit of the family and especially of the husband. Even in England this is sometimes the

case. How much more likely to be so in India, where the mother not only occupies a lower position in the household, but has not the knowledge which would enable her to spend a maternity benefit wisely?

The following are suggestions as to how employers could mitigate the conditions of expectant mothers:—

(1) By providing light work during the later months of pregnancy, which the woman could do without standing.

(2) By providing one free meal a day or milk from a good source to expectant mothers during the last two months.

(3) By having a simple maternity home attached to the mill premises. Each mill should have a crèche for receiving young children while their mothers are at work. Even now crèches are attached to 13 of the Bombay mills. It would cost little to have one or two airy rooms attached to the crèche and either keep a midwife to attend to the women or allow their own *dai* to come and attend them. As compared with confinement in the *chawls* they would have space, fresh air, good food and rest from home duties; as compared with hospital, it would at least be adequate for normal labour and would probably be taken better advantage of than the hospitals, where comparatively few mill-workers go for delivery.

(4) As regards maternity benefits these would be probably best given in kind, as indicated above—free meals, accommodation for confinement, food during the period of confinement, and a money present when returning home, sufficient to allow the mother a month's rest after delivery.

But if a maternity benefit of two or three months' wages is to be given, let it not be dependent on the women remaining at work until the end of the 8th month and returning one month after delivery. If she has worked in the mill a full year, why should the benefit not be given her at any time of her pregnancy when she wishes to leave off work and without securing any promise for the resumption of work? It would thus be in the nature of a bonus for work done. Half would be given when she left off work and half when the child was born. If she is required to remain until the end of the 8th month, harm will ensue in many cases, while the condition that she must resume work a month after delivery will assuredly mean neglect of the baby unless she has a female relation at home to take charge of it or unless there is a mill crèche.

The benefit, in whatever shape, should be strictly dependent on the mother having a full examination by a woman doctor, not only in order that her pregnancy may be certified, but in order that any danger or abnormality may be seen and provided for. This would also allow of propaganda being carried on and instruction given in the proper use of the benefit.

A Bill has recently been passed by the Bombay Legislature requiring that maternity benefits should be paid to all women mill-workers at confinement, the benefit to consist of two months' wages, that is leave on full pay for a month before and a month after confinement. While welcoming the action, one cannot help regretting the form in which the benefit is given for the reasons already declared. The woman is handed a cash benefit and no effort is made to tell her why, or to ensure that her own health or the child's will be safeguarded. It is not impossible, even yet, to amend the proposals of the bill.

The benefit now provided by legislation is Rs. 21 per head. There are about 30,000 women mill-workers in Bombay, of whom it is estimated about 10 per cent. bear children annually. Thus the amount to be given by the mill industry towards the benefit (if all women eligible came forward, which is unlikely) would be about Rs. 60,000 annually. A proportion of this sum would be sufficient to finance a large enquiry on the lines given above and to obtain ample evidence as to the best method of giving maternity benefits in India. Surely such an enquiry would be a wise preliminary of any widespread scheme for maternity benefits.

In the course of our investigation we were impressed by the fact that improvement in the conditions of the male workers would in itself assist the maternity troubles of the women. The lack of proper nourishment in pregnancy and the need for continuing work when physically unable is often due to the habits of the men who spend their own wages on drink or gambling, so that the wife practically supports the household. The provision of cinemas or other amusements for Sundays and holidays, the starting of welfare organizations, propaganda to inculcate a sense of responsibility towards the wives and children would all be means to this end. Work of this kind is already being carried out by the Y. M. C. A. in Bombay, but our point is that it should be done by the employer for the benefit of the worker. Grain shops in the mills would ensure the workers getting a good return for their money, and schools for the workers' children would be specially useful as inculcating on impressionable minds a sense of greater responsibility both in regard to work and social relations.

In concluding, we wish to express our thanks to Dr. Lucy Wills for much help and advice, especially with regard to tables and to the facts about diet obtained in the course of a larger enquiry which she is carrying out.

A CLINICAL STUDY OF POST-KALA-AZAR DERMAL LEISHMANIASIS.

By L. EVERARD NAPIER, M.R.C.S. (Eng.), L.R.C.P. (Lond.),

Kala-azar Research Worker (Indian Tea Association Endowment),

and

C. R. DAS GUPTA, M.B.,

Assistant, Kala-azar Ancillary Enquiry under Indian Research Fund Association.

(From the Calcutta School of Tropical Medicine and Hygiene.)

EIGHT years ago Brahmachari (1922) reported a case, a man with nodular skin lesions all over the body in which leishmania had been demonstrated. This patient gave a history of having had kala-azar and of having been cured by a course of injections of sodium antimony tartrate. During the next year or two a few more single cases of a similar type were encountered and reported, one by the senior writer (Knowles, Napier and Das Gupta, 1923). From the latter half of the year 1925 onwards an increasing number of patients suffering from this condition have attended at the School of Tropical Medicine and Hygiene for diagnosis and treatment. Colonel Acton and the senior writer (Acton and Napier, 1927) published a paper describing three distinct clinical types and discussing the pathology of this condition; in this report they analysed 44 cases. Since the publication of this paper Brahmachari (1928) has described yet another clinical type.

Our reason for writing this paper is threefold. During the last two and a half years we have seen, and have made and collected notes on, some 150 more patients suffering from this condition; these 150 cases include some previously undescribed clinical types; and, finally, we have realized the necessity of publishing further notes on this comparatively common condition with which the general practitioner in Bengal does not appear to be very familiar, if the diagnoses made before patients attend this institution are fair samples. Our previous paper was published in the *Indian Journal of Medical Research* and was probably not seen by a very large percentage of the readers of this *Gazette*. We propose to make this a purely clinical study.

Ætiology of post-kala-azar dermal leishmaniasis.

The condition has so far only been observed in kala-azar endemic areas. In this School we have seen well over two hundred cases whereas only 3 or 4 other cases have been reported in the literature. One case has been reported from Assam and so far none from Madras, to mention the other two endemic areas in India. We believe that a few other cases have been diagnosed in Assam and in the series now being reported two of the patients came from that province.

Persons of all ages, both sexes and all classes of the community appear to be equally susceptible. Indians, Anglo-Indians, Armenians, and Europeans have suffered from the condition; no community seems to be immune.

The condition is a sequela of a generalized leishmania infection. The majority of the patients give a history of having suffered from—and of having received treatment for—kala-azar, others give a history of having suffered from a definite attack of fever and splenic enlargement, whilst a very small number give no history of any such attack. As there appears to be no clinical difference between the cases in which there was and those in which there was not a definite history of kala-azar, the conclusion that all of them have at some time or another suffered from a generalized leishmania infection which in some instances cleared up without treatment, and which in others gave rise to symptoms so mild that they were forgotten or even not noticed by the patient, appears to be justified.

The dermal lesions usually make their appearance from one to two years after all the signs and symptoms of the visceral infection have disappeared. We have heard of no case in which the dermal lesions developed during the primary visceral attack, but in three instances which have come to our notice the visceral disease appeared to relapse at a time when the patient was suffering from dermal lesions.*

In every instance in which a thorough search is made *Leishmania donovani* can be demonstrated in the nodular lesions; in the depigmented patches the parasite cannot usually be found by means of a smear, but in a number of instances leishmania have been obtained from a culture of a skin snip from a purely depig-

mented lesion. There is little doubt that the parasite is *Leishmania donovani* and not one of the other species of the genus *Leishmania*; Das Gupta (1927) and others have demonstrated that when inoculated into mice the culture from a dermal lesion produces symptoms similar to those produced by the culture from a case of kala-azar.

Certain other points in the ætiology of the condition will be discussed later in this paper when the details of the present series of cases have been analysed.

Description of the different lesions encountered in post-kala-azar dermal leishmaniasis.

(1) *The depigmented area.*—A small partially depigmented area, varying in size from a pin-point (Plate I, fig. 1) to an extensive area occupying the whole of one aspect of a limb (Plate I, fig. 2), but usually about 1 centimetre in diameter. They commence as small pin-point areas and increase in size, not often to a greater size than 1 centimetre, so that they are usually discrete but occasionally they increase beyond this, coalesce, and produce the map-like appearance of Plate I, fig. 2. The depigmentation is not progressive so that complete depigmentation is not seen. At first the lesions are macular in type, but later become very slightly raised, the pre-nodular type of lesion. The anatomical distribution of these lesions is shown in the analysis of our cases, below.

The erythema or butterfly rash. (Plate I).—There is an erythema which varies in intensity in different individuals; in some it is very striking, in others noticeable only when attention is drawn to it. Though it is constantly present the patient will sometimes give a history that it is far more prominent after the face has been exposed to the sun. The distribution of this erythema is very constant, namely on the cheeks, the skin surfaces of the upper and lower lips, and the outer surfaces of the alæ nasi; occasionally it extends on to the tip and sides of the nose and the chin.

The nodules (Plate II, figs. 3 and 4).—These are soft granulomatous growths, yellowish-pink in colour, varying in size, but usually about the size of a split pea. The nodules may join and form plaques (Plate II, fig. 3). The skin over the nodule is thin and glossy, but shows no special susceptibility to break down and heals rapidly after a portion of it has been removed for diagnostic purposes. The nodules are painless, but there is no anaesthesia. They appear on all parts of the body but mostly on the face. The best idea of the frequency with which the nodules appear at different sites can be obtained from the analysis of the present series which is given below.

These three are the most common types of lesion; the rarer types are described below:—

The verrucose type (Plate II, fig. 5).—Warty growths occur at the root of the nails on the fingers and toes, and there is considerable thickening of the distal phalanges of the digits;

* Recently Brahmachari and Banerjee (1929) have reported one such case. The patient was originally treated for kala-azar with sodium antimony tartrate by the senior writer, remained free from all symptoms of dermal leishmaniasis for 2 years, he then developed dermal lesions, and was given 3 courses of treatment, including one of urea-stibamine, without showing any improvement. He drifted away from our institution, he developed signs of visceral infection again and was then treated by Dr. Brahmachari. Again the signs of visceral disease disappeared, but the dermal lesions remained. He eventually responded to a very prolonged course of antimony injections; the photographs show him to be entirely free from nodular lesions on the face.

PLATE I.

Fig. 1.

Fig. 2.

Fig. 5.

condition is usually diagnosed as a tubercle.

The papillomatous type (Plate III, fig. 6).—Instead of the ordinary nodular growth there is hypertrophy of the individual papillae of the skin with the production of a rough, dry area consisting of minute papillomatous growths. This is usually seen on the nose or chin.

The hypertrophic type.—In this the lips, eyes, or alae nasi become hypertrophied as if there were lymphatic obstruction of the part. They form soft lipoma-like swellings which do not pit on pressure (Plate III, figs. 7 and 8). In one variety of this type the nose is involved; there is a general hypertrophy of the tip of the nose, the skin is stretched and the tumour presents a mottled appearance like a gooseberry (Plate IV, figs. 9 and 10). In the sites where this particular type of lesion occurs the mucous membrane is continuous with the skin and the former appears to be involved in the infection. In the case shown in Plate III, fig. 7, the parasites were obtained for a scraping from the mucous surface of the lip and in the case shown in Plate IV, fig. 9, in a smear from inside the nose.

The xanthoma type.—The lesions present the textbook description of those of xanthoma tuberosum multiplex. There are raised orange-coloured plaques on different parts of the body, most noticeably at the bend of the elbow, on the axillary folds, on the inner side of the thigh, at the outer canthus of the eye, on the chin and at the angles of the mouth. They are painless and do not ulcerate. In a type of the disease which might be classed under this heading there are large raised plaques on different parts of the body which do not undergo the same colour change, but which become completely depigmented.

The relationship of the different types of lesion.

As far as the trunk and limbs are concerned the depigmented patches are the first to make their appearance. These patches tend to increase in size and in some situations they are replaced by nodules. Although depigmented lesions are very common on certain parts of the body below the neck—the back, arms, forearms and thighs—nodules are extremely rare; it seems obvious, therefore, that in these situations the depigmented areas seldom go on to nodular formation, but remain without undergoing any change for a considerable time. These lesions appear usually about one year after the kala-azar attack, but in some cases the interval appears to have been longer; this can be explained partly by lack of observation on the part of the patient.

On the face depigmented patches are frequently the first manifestation but occasionally these are preceded or accompanied by the butterfly erythema referred to above. When this erythema disappears it may leave scattered nodules or depigmented patches, usually both.

The erythema and the depigmented patches may be considered as the first stage of the disease, the nodular the second stage.

The nodular lesions appear on an average about two years after the kala-azar attack—they are usually preceded by depigmented patches or the erythematous rash, but are sometimes the primary lesions. A few patients have returned within a year of treatment for kala-azar with an extensive nodular eruption.

The xanthoma stage would appear to be the final outcome of this condition, but the comparative rarity of this type suggests that only a small percentage of cases go on to this stage. The history in these cases is usually from 10 to 30 years.

The other types described are probably not stages in the disease so much as special manifestations due to the particular anatomical distribution of the foci of infection; the verrucose type occurs in the terminal phalanges of the digits, the hypertrophic in the eyelids, lips, etc.

Diagnosis.

The depigmented lesion and the nodule are so typical that after a very little experience they are easily recognized clinically. It is not easy to find the parasite in the depigmented lesions, in fact we have never yet seen the parasite in a smear made from one of these lesions, but by snipping out a piece of skin and dropping it into an N.N.N. tube, under strict aseptic precautions, a culture can usually be obtained. The confirmation of the diagnosis of a nodular lesion is much simpler; a portion of a nodule is cut off with a pair of scissors and a smear made from the cut surface, the smear is stained by Leishman's or Giemsa's stain and leishmania parasites are usually found without difficulty. In some nodules the parasites are scanty and a prolonged search may be necessary. The atypical lesions can only be diagnosed by finding the parasite.

The present series.

This series consists of 150 cases. The patients attended for treatment at the Calcutta School of Tropical Medicine between October 1927 and February 1930, a period of about 28 months. The previous paper on this subject, referred to above, was submitted for publication in March 1927; it was a report on 44 cases. Between March and October a number of patients attended, but as the senior writer was on leave no special notes were kept.

The presence of parasites.

In most of the nodular cases an attempt was made to confirm the diagnosis microscopically; in some, however, in which nodules were scanty, even though the first smear did not show parasites, if the condition was clinically typical, the clinical diagnosis was accepted. In a few of the cases in which depigmented patches

were present, the diagnosis was confirmed by cultural methods, but this was not done as a general rule. There is little likelihood of mistakes having been made on this account as the condition is so characteristic and the few cases in which there was any doubt were excluded.

Leishmania was demonstrated in 81 cases and in 69 the diagnosis was clinical only. We have divided the cases into two groups. A, being those diagnosed microscopically and B, those diagnosed clinically. It will be seen that these two groups are in every way similar and it is, therefore, almost certain that the aetiology in the clinically diagnosed group is the same as in the other.

Nature of the lesions.

The cases can be classified as follows:—

The distribution of the lesions.

A. In 15 cases there were nodules on the trunk or limb, in 63 nodules on the face and depigmented patches on the body, and in 1 nodules on the face only.

B. In 3 cases there were nodules on the trunk or limbs, and in 28 on the face only.

The distribution of the lesions on the various parts of the body is shown in the following table (Table II):—

It is thus apparent that nodules are the more common lesions above the shoulders, and the depigmented spots below. The nose, chin and cheek are the usual sites for the nodules, whereas the depigmented patches are found on the back, arms, forearms and thighs, a little less frequently on the chest, legs, shoulders and

febrile attack with splenic enlargement, but a very few gave no history of fever at all. The table below gives further details of the histories:—

Excluding one case in which the history was 36 years, the average lapse of time between the attack of kala-azar and the first attendance for the dermal condition was 3.45 years in the cases showing nodules and 3.28 in those with only depigmented patches. There is very little difference between these two figures; this suggests that the depigmented patches do not by any means always develop into nodules.

The incubation period.—In kala-azar the parasites are distributed widely and can be found in practically every tissue and organ in the body, but for some reason even in chronic cases of the disease no development in the skin sufficient to produce local lesions appears to take place. Presumably, therefore, this development commences when the visceral infection disappears. For those cases in which a history was obtained the time that elapsed between the conclusion of treatment for kala-azar and the first observation of the skin lesions is shown in the following table:—

This is also shown graphically in Graph I.

The mean of the lapse of time between the disappearance of the symptoms of visceral leishmaniasis and the appearance of the lesions of dermal leishmaniasis is 1.88 years. It must be remembered that a large number of the patients will not have noticed the early lesions so that the actual time is probably less than these figures indicate. In 88 per cent. of patients the lesions appeared within three years of the kala-azar attack.

The relationship to treatment.

The majority of the patients gave a clear history regarding the treatment they had received, but a few could only state that the injections were "white, like water," or "red," as the case might be. These were entered as sodium antimony tartrate or urea stibamine, respectively. The following table gives details of the treatment which the patients had received (Table V):—

Of the 112 patients who had received treatment 2 had definitely received an insufficient number of injections, and 24 had received less than the usual course, but sufficient to produce a 70 or 80 per cent. cure rate. As a very large percentage of patients fail to complete their course of treatment, there is nothing in these figures which suggests that insufficient treatment is a predisposing factor in the production of skin lesions.

Caste, sex and age.

The following table shows the caste and sex of the patients (Table VI):—

The sex distribution is very much that of the general out-patient attendance. In an analysis of 300 kala-azar out-patients (Napier, 1922) the total number of females was 45; this is almost exactly the proportion of females in this series.

Age distribution.

This is shown in tabular form below (Table VII):—

There is a very marked difference in the age distribution between those showing nodular

lesions and those showing depigmented lesions only; whereas 40 per cent. of the former are over the age of 30, only 1 patient or 2.7 per cent. of the latter are above this age. This is well shown in Graph II. Comparing the age grouping with that of the kala-azar patients attending the same institution, it will be seen that the dermal lesions are relatively much

more common in the later age periods; of the kala-azar patients 21 per cent. are in the first decennial period, whereas only 2.8 per cent. of the dermal cases fall in this period. Graph III shows the difference between the age grouping in the two conditions. The dermal leishmaniasis curve appears to be about 10 years behind the kala-azar curve. This cannot be accounted

Fig. 6.

Fig. 7.

Fig. 9.

Fig. 10.

for by the delay in development of the dermal lesions as the average is only about 2 years. It is obvious that as the age advances the patient becomes more liable to develop dermal lesions.

Discussion.

There is a considerable diversity in the type of skin lesion produced by this parasite—a number have been described and it seems very probable that many have not yet been recognized. The butterfly erythema was described by Dr. Brahmachari who thought that it was a manifestation of dermal infection with leishmania, because in the case he described it was associated with nodular lesions in which he was able to demonstrate the parasite, but the proof that his surmise was correct is provided in the analysis of this series of cases where this particular type of lesion is shown to be associated repeatedly with other dermal lesions caused by leishmania. On the other hand of the case in which the verrucose lesions were present one was diagnosed as dermal leishmaniasis on account of lesions in the face—the other lesions on the feet and fingers being diagnosed as tuberculides; it was almost by chance that the latter lesions were examined and also found to contain enormous numbers of leishmania. In the same way the diagnosis in the case shown in Plate III, fig. 7, was made during a routine examination of a cutting, and in the case of the girl in Plate IV, fig. 9, Dr. J. M. Henderson found leishmania in a smear made from her nasal mucous membrane which he was examining for lepra bacilli. Nevertheless, the typical lesions in this condition are so characteristic and the cases are, comparatively speaking, so common that it is still a matter of the greatest surprise why they were overlooked for so long and why they are so rare or, at any rate, so rarely reported in other kala-azar endemic areas.

The constant association of this condition with a history of kala-azar, together with the presence of the parasites morphologically and culturally identical with those of kala-azar, has led to the assumption that the dermal condition is a sequel of kala-azar. The only other explanation which seems at all possible is that the skin condition is caused by a subsequent infection with leishmania in a patient who has already acquired a degree of immunity to systemic infection. The widespread nature of the lesions and the fact that they appear so constantly in covered parts of the body make it certain that in the genesis of the condition there must at some time have been a generalized infection. In this series 80 per cent. give a history of a previous attack of kala-azar, whereas in the previous smaller series only about 50 per cent. gave this history. Graph I shows that there is a very definite association between the kala-azar attack and the onset of the dermal lesions, the peak of the curve being

at the first and second year. The lesions develop slowly, and it is quite comprehensible that, commencing when the generalized infection subsides, they would take this length of time to become clinically noticeable, whereas it is difficult to understand why, if it is a case of reinfection, this should occur at so constant an interval after the primary kala-azar attack.

GRAPH I.

Time between kala-azar attack and onset of symptoms of dermal leishmaniasis.

There is no evidence whatsoever that the treatment plays any part in causing this condition to develop in a kala-azar patient. The condition occurs in persons who give a typical history of an attack of kala-azar but who had no treatment for the disease, no one form of treatment appears to produce any special susceptibility towards the disease, nor is there much evidence that insufficient treatment is a predisposing factor.

In this analysis only one point regarding the epidemiology of the disease has come out—that is the later age incidence of dermal leishmaniasis as compared to kala-azar and the marked difference between the age incidence of the nodular and that of the depigmented lesions (Graphs II and III).

Acknowledgments.

A very large percentage of the cases in this series were sent on to us from either the Skin Disease Out-Patient Department or the Leprosy Department of this School. We take this opportunity of thanking the officers in these departments for the assistance they have thus rendered us.

Our thanks are also due to Dr. A. Basu for some help in note taking and smear examination.

THE DIFFERENTIAL DIAGNOSIS OF LEPROSY AND DERMAL LEISHMANIASIS.

By E. MUIR, ch.B. (Edin.), F.R.C.S. (Edin.),

Research Worker in Leprosy, School of Tropical Medicine and Hygiene, Calcutta.

DERMAL LEISHMANIASIS was first described by Brahmaehari (1922) and later in more detail by Acton and Napier (1927). The first case described by Acton and Napier in their paper was originally brought to the leprosy clinic at the Calcutta School of Tropical Medicine under the supposition that he was suffering from leprosy. Since then patients suffering from this disease have frequently been sent to the leprosy clinic. Up to the end of 1928 the number of these patients was not recorded, but thereafter an accurate record was kept, and it was found that during the first 10 months of 1929 nine such cases appeared, while during November no fewer than five supposed cases of leprosy were diagnosed as suffering from dermal leishmaniasis. Out of these fourteen cases we found *L. donovani* in the skin of eight cases, while in the remaining six the diagnosis was made from clinical signs.

In three cases, seen previous to 1928, both leprosy and dermal leishmaniasis were present at the same time.

There are two types of dermal leishmaniasis lesions which are apt to be confused with corresponding leprosy lesions:

(1) Depigmented skin areas. In early cases of leprosy, especially in children, depigmented patches often appear, which are bacteriologically negative and without any definite signs of anaesthesia that can be detected. Such cases are diagnosed only because of a very definite history of contact with an infectious parent, or by the lesions taking on subsequently more definite signs of leprosy. It is this type of lesion from which the depigmented areas of dermal leishmaniasis have to be distinguished. In leprosy the areas are larger and fewer in number; and show signs of growth at the margin, which however fades more gradually into the surrounding dark skin than it does in the other disease. They tend to be situated more on the extensor surfaces of the body.

In dermal leishmaniasis on the other hand the depigmented areas are smaller and often punctate. They are more numerous and tend to cluster round certain areas such as the nose, mouth, chin, the inner sides of the thighs and

the shoulders and scapular regions. The margin is somewhat more clearly defined than in leprosy. The skin of this type of lesion is not generally positive for *L. donovani*.

(2) The nodular type of dermal leishmaniasis (called the "xanthoma" type by Acton and Napier) has been even more frequently mistaken for the nodular type of leprosy. The lesions are similar in distribution, but have a like tendency to group themselves round the nose and mouth, only that in the former disease the ears are comparatively exempt, whereas in leprosy, when the nose and mouth are thickened or nodular, the ears also are almost invariably thickened and nodular also. The differential diagnosis in this type of lesion is not difficult to make, as in leprosy large numbers of acid-fast bacilli are present, while in leishmania *L. donovani* can generally be found in a smear. In the latter disease another useful diagnostic point which is generally present is a history of kala-azar having occurred a few years before.

Fig. 1. Dermal leishmaniasis.

Photographs are given of a patient who for 35 years suffered all the mental distress which the social ostracism of leprosy implies. When 10 years of age he suffered from a severe attack of fever, and this was followed by the appearance of depigmented patches which later became red and thickened. The patient was brought as a case of leprosy for consultation, and the

writer at first sight was inclined to confirm the diagnosis. But the comparative freedom of the ears from nodulation, the fact that the lesions of the arms were on the flexor and not on the extensor surfaces, and the absence from

Figs. 2 and 3. Front and back views of the patient shown in Fig. 1.

the hands and feet of all signs of anæsthesia, which would certainly have been present if this case had been one of leprosy, threw doubt on this diagnosis. Microscopic examination of a smear made from one of the nodules, instead of showing acid-fast bacilli, showed great numbers of *L. donovani*.

As the dermal form of kala-azar yields almost as readily as the visceral form yields to antimony treatment, the unnecessary distress suffered by this patient has provoked the writing of this paper. It is not unlikely that in the endemic areas of kala-azar many other patients are being treated for leprosy, or suffering, untreated, under its stigma, who might be relieved and rapidly cured if a correct diagnosis were made.

A NEW CASE OF *BERTIELLA STUDERI** IN A HUMAN BEING.

By P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.T.M.
 (From the Hookworm Research Laboratory, Calcutta School of Tropical Medicine and Hygiene, supported by the Indian Jute Mills Association.)

A PORTION of a tapeworm was sent by Capt. N. N. Ghosh of Naryanganj for identification. The history was that a boy eight years of age had been passing similar bodies at intervals of a week or so for some time past. The specimen consisted 14 segments of a tapeworm and it was 8 mm. in length and 10 mm. in breadth. It was fully gravid and all organs except the uterus, loaded with eggs, had disappeared. Eggs removed from the specimen had the appearance of the eggs of *Bertiella studeri* and their dimensions corresponded with those given by Chandler (1925) for the eggs of this species.

At the request of the writer Capt. Ghosh treated the patient with Ext. Filix Mas and almost the complete worm was recovered. It measured 28.9 cm. in length, and the posterior 4 cm. were 14 mm. in breadth. The head was not found in the bottle in which it was forwarded, but a small piece from the anterior end of the strobila consisting of seventeen segments was detached from the worm, so it is possible that the head was there also, but had been lost.

Mature segments were well extended, being 1.45 mm. in length and 3 mm. in breadth. The dimensions of this part of *B. studeri* given by Faust (1929) are 0.075 mm. in length and 6 mm. in breadth. At first sight these measurements appear very different, but any one who has observed a living tapeworm must be familiar with the great alterations in shape that these worms are able to produce in themselves by alternate contraction and relaxation of the transverse and longitudinal muscle fibres, so that length and breadth of segments alone are very unreliable as a diagnostic character. If the surface area of the mature segments of the writer's specimen are worked out by multiplying the length by the breadth it gives a figure of 4.35 square millimetres, and if Faust's measurements are treated in the same way an area of 4.5 square millimetres is obtained, dimensions which are closely comparable. From this observation it is suggested that possibly a more reliable guide in the diagnosis of Cestodes would be to give the surface area of a segment in square millimetres instead of its length and breadth.

On account of the longitudinal extension of the worm the sexual organs have a slightly different appearance from that figured for *B. studeri*, where the marked lateral extension and consequent longitudinal shortening of the segments compresses the ovaries laterally and shortens them antero-posteriorly. But if

* Baylis (1929) gives *B. satyri* as a synonym of *B. studeri*, and the writer has followed this nomenclature in the present paper.

Fig. 1. Photograph of worm. $\times 4$.

Fig. 2. Mature segments. o, ovary, r. s. receptaculum seminis, t. testes, ut. uterus, v. g. vitelline gland

allowance is made for the more extended condition of the writer's material these organs have the characters of *B. studeri*. The testes are approximately the same number, and the vagina, cirrus pouch and vas deferens appear the same. A further point of similarity is that the gravid segments are identical and the eggs are the same size as in *B. studeri*. Therefore, although the head was not obtained, it is considered there is little doubt that the writer's specimen is one of *B. studeri*.

Two previous records of this species of worm from human beings are in existence.* The first is by Blanchard (1913) who obtained a specimen from a girl aged eight years at Port Louis, Mauritius, and the second record is by Chandler (1925) who obtained his specimen from a female Hindu child aged two years in Bengal. It is of interest that all three records are from young children. The only other record of a member of this genus being found in a human being is that of Cram (1928) who identified a worm as *B. mucronata*, which had been passed by a young Spaniard in Cuba.

A NOTE ON AN APPARATUS DESIGNED TO TAKE SAMPLES OF WATERS FROM WELLS, TANKS, ETC., AT STATED DEPTHS.

By R. B. LAI, M.B., B.S., D.P.H., D.T.M. & H., D.B.,
Epidemiologist to Government, Punjab,
and

PT. DAULAT RAM,
First Laboratory Assistant.

(From the Epidemiological Bureau, Punjab, Lahore.)

It is generally recognized that the surface water from a well or tank is not a fair sample of the average quality of its water. It is, therefore, of considerable importance, especially when taking samples for bacteriological examination to obtain water from a depth of about 3 feet from the surface and to avoid contamination from the upper layers. Various apparatuses have been designed for this purpose,

some of which require evacuated sealed flasks, while others involve complicated rubber connections and are, therefore, not suited for general use in this country. Moreover, in almost all the apparatuses described in the textbooks, there is no arrangement to close the opening through which the water enters the bottle or the flask when it is withdrawn, and there is no absolute surety of the container getting completely filled at the required depth. There is, therefore, a certain amount of risk of contamination from the surface water when the apparatus is withdrawn.

A simple apparatus has been designed for this purpose and is described below.

It consists essentially of four parts (see diagram).

(1) A cylindrical copper case A for the body of the bottle B. The bottom of the case can be opened on a hinge to admit the bottle and there is a circular hole in the top to allow the passage of the neck of the bottle and the stopper. Around the hole there are three hooks to afford attachment to the three suspending cords and in between them are fixed vertically three metal bars each about 3 inches long which could be joined together by means of a triangular piece.

* After this paper went to press a paper appeared in *The Indian Medical Gazette* of April by Major Sharma, I.M.S., in which he records the finding of the eggs of *Bertiella satyri* in three out of 503 people examined at Shillong.—Ed., I.M.G.

(2) *A stopper holder C.*—This is a triangular piece of copper plate with truncated angles. It has a clip D to hold the stopper on its under surface, and a metal rod fixed in the centre on its upper surface. The latter affords attachment to the central cord and gives additional weight to the stopper. In the angles there are three holes guarded by tubes to receive the vertical metal bars.

(3) *A stopper-float E.*—This is a wooden disc about three-quarters of an inch thick and a foot in diameter. There is a hook on its under surface, for the other end of the central cord and three holes at equal distance from each other near the periphery to allow free passage to the three suspending cords. Small reels are provided to wind up the cords when the apparatus is not in use.

(4) *System of cords.*—There are four of these, one a central cord F which is attached at its upper end to the hook in the float and at its lower end to the central bar of the stopper holder. Then there are three suspending cords G. These are attached to the hooks in the upper surface of the cylinder at their lower end and are joined together at the upper end after passing through the holes in the stopper float. They have knots below these holes on which the float can rest. Their lengths are so adjusted that when the float is resting on the knots, the central cord is loose. Instead of tying the cords to the hooks, small watch-chain-hooks are provided for the purpose. The material of the cords is selected so that they will not twist by themselves.

An 8 oz. stoppered bottle which fits loosely in the copper case is thoroughly cleansed and placed in the metal cylinder. The stopper holder is applied to the stopper and pressed to catch it. The nuts and the triangular piece are screwed on the free ends of the metal bars and so adjusted that on lifting the stopper holder the mouth of the bottle is freely opened for the water to fill. The stopper is released from the stopper holder and little pieces of paper introduced in the mouth of the bottle to prevent the stopper getting jammed. The apparatus is now sterilized and the cords are hooked on. The distance between the mouth of the bottle and knots on the suspending cords will determine the depth of water at which the stopper will open and can be adjusted as desired, changing the size of central cords accordingly.

The stopper holder is again pressed on the stopper to catch it and the apparatus is now ready for use and can be lowered into a well or tank by means of a suitable cord or rope attached to the suspending cords. The bottle sinks directly on account of the weight of the copper case. The stopper float on reaching the surface of water automatically buoys up the stopper holder with the stopper, thus opening the bottle. After a short while big bubbles suddenly rise to the surface as the water displaces the air in the bottle.

The bottle fills in a few seconds and the apparatus is drawn up when no more bubbles appear. Sometimes a few short jerks may be required to open the stopper if it fits too tightly. As the float is lifted up from the surface of the water it drops back on the knots of the suspending cords thus loosening the central cord, the stopper holder falls back and automatically stoppers the bottle. This ensures prevention of contamination from the upper layers of water.

The stopper is then released from the stopper holder, the bottom lid is opened and the bottle is removed. It is properly labelled and sent back to the laboratory in a suitable case.

The following advantages may be claimed for this apparatus:—

1. It is cheap and easy to make.
2. It works automatically and can be entrusted to even untrained sample collectors.
3. It ensures exclusion of surface water.
4. It can be thoroughly cleansed and easily sterilized.
5. It can be adjusted to draw samples from stated depths within ordinary limits.
6. There are no parts likely to go out of order.

The apparatus can be suitably modified if samples are to be taken from bores of small diameters or great depths.

Note.—The apparatus can be obtained from the Upper India Scientific Works, Chamberlain Road, Lahore.

PROTEIN REACTIONS OF BACTERIA.

(A plea for their routine use and intensive study.*)

By S. N. GORÉ, L.M. & S. (Bo. Univ.),
Assistant Director, Haffkine Institute, Bombay.

INTRODUCTION.

Just as a chemist does not attempt to determine the constituents of a substance before he is certain of its purity, so will a bacteriologist not commence to work on the biological action of a bacterium until he satisfies himself of the purity of a culture.

The purity of a substance is ensured by means of repeated crystallization, and the purity of a bacterium by repeated plating. Further, just as the chemical is subjected to a melting point test or spectroscopic and other examinations to establish its purity, so too are the uniform bacterial colonies further subjected to staining reactions, morphological examination and cultural tests.

Among these last, biochemical reactions form an important part. Now reference to the literature will show that while practically all the attention has been focused on the carbohydrate reactions, very little heed has been given to protein reactions. The reasons are not far to seek.

A great variety of pure carbohydrates have been isolated or prepared by chemists and they were so much ready relatively cheap material to be used by Castellani in the identification of intestinal bacilli (*vide* his table) (1).

In the case of proteins chemists have only succeeded so far in isolating or preparing a few amino-acids and producing fractions which are

*Being a paper read at the Medical and Veterinary Research Section of the Indian Science Congress, Allahabad, January 1930.

very complex mixtures of little known constituents. Amino-acids by themselves do not suffice as bacterial nutrients and further they are far more costly for routine use than the majority of carbohydrates. Hence the necessity of falling back upon fractions formed by the partial hydrolysis of proteins which will act as bacterial nutrients and whose price will not be prohibitive.

The protein material available for protein reactions are the different brands of peptone. The protein reactions referred to in this note are (1) Indole, (2) Hydrogen sulphide, (3) Nitrite, and (4) Cholera-red. In Table I are shown the sources of these products, and the reagents commonly used in their detection.

TABLE I.
Protein in reactions.

Product.	Source.		Reagent.
	Organic.	Inorganic.	
Indole	Tryptophane		Ehrlich's aldehyde.
Hydrogen sulphide	Cystin, cystein	Sodium sulphide	Lead acetate.
Nitrite	Protein matter	Sodium hyposulphite	
Cholera-red		Sodium nitrate	Usoy's solutions.
		Indole + Nitrite	Strong HCl.

From this table it will be seen that indole has only one source, viz., the amino-acid tryptophane, while hydrogen sulphide and nitrite have more than one source in both the classes of substances.

All these reactions, though known for a long time, have not yet received the recognition they deserve.

Besides their utility in the identification of bacterial species, they deserve special consideration because they are likely to throw light on the correlation between *in vitro* and *in vivo* reactions.

Such a possibility, long conjectured by the author, has now received such experimental support as to justify its being brought to the notice of the Indian Science Congress.

In passing it may be remarked that among the indoligenous bacteria there are far fewer pathogens than among the hydrogen sulphide- and nitrite-producing bacteria; the former group contains many putrefactive and the typhoid-paratyphoid-enteritides bacteria, while the latter group contains, besides the cholera vibrio, *B. pestis*, some members of the Pasteurella group of bacilli, and the diphtheria bacillus.

1. Indole.

Indole which was first applied as a differential test between *B. coli* and *B. typhosus* by Kitasato as far back as 1889, has only recently been recognised as a dependable test.

Regarding this test the Committee of Bacteriological Technique of the Society of American Bacteriologists in their 1926 edition of the *Manual of Methods for Pure Culture Study of Bacteria* write:—"The indole test has long been considered one of the least satisfactory of those employed in pure culture study. Recent years, however, have seen considerable work on the test, as for example that of Ziprel (1912), Frieber (1921), Fellers and Clough (1925), Goré (1921), Holman and Gonzales (1923), Kulp (1925), and Koser and Galt (1926); and as a result it can now be used more intelligently than in the past."

"It is recommended that the Goré and the Gnezda tests be used in a routine way. (Results

with these two tests agree closely as shown by Kulp) The Ehrlich test unmodified is less specific for indole than the Goré modification or the Gnezda test." (2)

With respect to the three methods of testing for indole referred to by the Committee, Koser and Galt write:—"Of the several indol tests employed in our work we are inclined to favour the Goré method as the most satisfactory which may be used where large numbers of cultures are to be examined. It possesses most of the advantages of the oxalic acid method and in addition it is more delicate and the colour of the positive test is deeper and more striking than the pink tint of the oxalic acid paper.* In our hands the Goré test has never yielded the confusing colours or false positive tests that are secured when the reagents are added directly to the culture,† and at the same time appears to be as delicate under these conditions. Also, it has given pronounced and striking positive tests when applied to agar slant cultures of indol-producing organisms, even when a peptone of low tryptophane content was used in the medium." (3)

The Cotton Wool Plug Test was devised by the author in 1920 and was based on the facts that indole was volatile and that Ehrlich's aldehyde was the most delicate reagent for it. In 1921, this test was critically studied along

* That is the Gnezda test.

† Ehrlich's test.

with eight other tests, by Malone and Goré, and as a result of this study they concluded that "The method which combines delicacy and specificity, and best fulfils the conditions laid down for a routine test is that described under the heading 'Goré's Cotton Wool Plug Test.' Under the conditions of these experiments and in actual practice it has been found to be a simple, delicate and reliable method."

Regarding the inhibitory influence of nitrite on the Ehrlich test, they wrote, "As Marshall pointed out, the Ehrlich reaction is inhibited by the presence of nitrites, and this fact should be borne in mind when testing cultures of cholera and cholera-like vibrios in ordinary broth. We have found that there is a definite (quantitative) relation between indole content of a culture and the amount of nitrite sufficient to cause the total inhibition of the rose-indole reaction, i.e., with small amounts of indole correspondingly small amounts of nitrite will inhibit the colour reaction."

"It is unsafe to apply the Ehrlich reaction to nitrate broth cultures, as a large number of bacteria are capable of reducing nitrates to nitrites. It appears, however, from the following experiment that this object is not valid if the Cotton Wool Plug Test be applied."(4)

Test applied.	Twenty-four hours culture of 1 per cent. Fairchild's peptone nutrient broth containing 0.1 per cent. potassium nitrate.	
	<i>B. coli.</i>	<i>V. cholerae.</i>
Ordinary test (Ehrlich's).	Yellow colour.	Yellow colour.
Chloroform extraction.	Faint trace of pink.	Faint trace of pink.
Steensma test ..	No trace of pink.	No trace of pink.
Goré's test • ..	Rose colour.	Rose colour.

Thus when the Ehrlich test is performed in the culture itself, the nitrites destroy the reagent and in consequence no pink colour develops. In the Goré test, the reagent is outside the reach of the destructive influence of the nitrite and is consequently available for the volatilised indol to act and colour the cotton wool pink.

In spite of these advantages of the Cotton Wool Plug Test being established in 1921, and confirmed by other workers in 1925 and 1926, in the latest edition of Muir and Ritchie's *Manual of Bacteriology*, edited in 1927 by Browning and Mackie, we find the Ehrlich test being performed in the same way as it was in 1906. They write:—"The Ehrlich test..... is of special value in dealing with organisms of the coli-typhoid group....The reaction is also obtainable with the cholera vibrio, but further

investigation is here necessary, as Marshall states that under certain circumstances the nitrites formed by this bacterium may have an inhibitory effect on the formation of the rose colour."(5)

Having devised a simple, delicate and specific test for detecting indole, and believing that a protein reaction would be as efficient a combination with carbohydrate reactions, as it is in a dietary, the author devised a three-culture scheme of grouping intestinal bacilli, and presented it at the Indian Science Congress held at Bangalore in 1924. In this scheme the primary grouping is based on the two most commonly used carbohydrates, viz., glucose and lactose, while the secondary groups are effected by combining with these carbohydrate reactions, a protein reaction, viz., indole and a carbohydrate reaction, viz., carbinol—the so-called Voges-Proskauer reaction. This scheme is shown in Chart 1.

The subgrouping and cultural identification of individual species was based on Castellani's Table of the Cultural Reactions of Intestinal Bacilli.(6)

Since the receipt of Bergy's *Manual of Determinative Bacteriology* and the study made in association with Malone of a large number of stools derived from healthy persons, as well as from cases of diarrhoea, dysentery and sprue, along the lines of the classification outlined above, the subgroupings were made more comprehensive than the previous ones.

The association of the protein reaction indol with the two most commonly used carbohydrate reactions so greatly facilitated the cultural identification of the intestinal bacilli, and stood in such great contrast with Castellani's tables in the cultural identification of intestinal bacilli, that one is tempted to apply to his scheme the famous French epicurian Brilliet Sararin's epigram "Tell me what you eat; I tell you what you are"; while to Castellani's tables may be applied another epigram suggested, as being more modern, by the late Dr. Priestly, viz., "Tell me what you are; I tell you what to eat."

It is obvious that bacteria when they are secured by us do not tell us anything except their source and morphology. Beyond this they are unable to give any further information as to their identity until we subject them to either of the above ways of recognising them.

2. Hydrogen Sulphide.

In 1924, a paper embodying the results of the bacteriological examination of the stools referred to above was read by Goré and Malone at the Critics' Club, Haffkine Institute. In the remarks made by Col. Mackie, he suggested the study of hydrogen sulphide production by the intestinal bacteria.

Accordingly, this reaction formed the second protein reaction which was taken up by the author for study.

CHART 1.

0 = No acid or gas production in carbohydrate media; 0 = No indole or carbinol production.
 g = Acid production in glucose I = Acid production in lactose.
 G = Acid and gas production in glucose I. = Acid and gas production in glucose.
 I = Indole production C = Carbinol production.

During the war period, when the author was in charge of the work in connection with the identification and confirmation of the bacilli isolated at the War Hospital in Bombay and other places, he had used both these reactions—viz., indole and hydrogen sulphide—routinely according to the methods prescribed in textbooks on bacteriology, but found the results to be not very consistent. In consequence, as little importance came to be attached to the reactions then, as we find to be the case in the present day textbooks on bacteriology.

In the course of a comparative study of the textbook methods of determining the hydrogen sulphide character of intestinal bacilli—which were again found to be as unsatisfactory as during the war period, it occurred to the author to apply the Cotton Wool Plug technique to detect hydrogen sulphide in peptone cultures, using lead acetate solution in place of Bohme's. (8)

This device not only succeeded as well as it had done in the case of indole, but allowed the detection of these two products in the same bacterial culture, leaving the culture available for further use; and as mentioned further on, this same peptone culture has been made use of in determining the presence of nitrite and the cholera red reaction. (7)

As far as is known at present, indole has only one source, from which it could be produced, viz., tryptophane, either in the free state and in a polypeptide or peptide form. Such is not the case with hydrogen sulphide. It may be produced from free cystin or cystein, or the presence of either amino-acid in a peptide or polypeptide, or from mineral salts, e.g., sodium hyposulphite or sodium sulphide.

An important point has not yet been sufficiently appreciated, that the availability of the sulphur-containing amino-acid in a peptone depends probably on its position in the peptone.

Thus a bacillus may produce hydrogen sulphide from one brand of peptone but not from another, though the sulphur-containing amino-acid is present in both the peptones.

The utilisation of the different sources of hydrogen sulphide for differential and identification purposes still remains to be adequately dealt with.

From a study made with four brands of peptone with the broth made from the acid meat digest and used in the preparation of Haffkine's prophylactic, with two commercial meat extracts, and with infusion of meat, it appears that, judged by their capacity to produce indole and hydrogen sulphide when acted upon by different kinds of bacteria, some of these products were found to give more constant results than others. This subject is being further studied and will form the subject of another paper.

3. Nitrite.

The third protein reaction to be referred to in this paper and which forms the major portion thereof is nitrite. Like hydrogen sulphide, nitrite may be produced either from an inorganic or an organic substance.

It may be pointed out here that while the general impression among bacteriologists with reference to hydrogen sulphide is that it is derived from an organic source, the reverse is the case with nitrite.

A reference to many of the textbooks on bacteriology will show that the presence of nitrites in bacterial culture is assumed to be due to reduction of a nitrate in the medium either added on purpose or present as an impurity.

It is only a few authors like Kendall and Muir and Ritchie who clearly state that nitrite in a peptone water culture of the cholera vibrio is derived from the peptone; and it is the presence of a nitrite so derived that contributes to the cholera-red reaction and differentiates a cholera culture from a *B. coli* culture. However, if a nitrate was present in the medium in which *B. coli* was grown, the culture would respond positively to the cholera-red reaction, which as is well known depends on the simultaneous presence of indole and nitrite in the culture.

With a view to make this distinction quite clear, the above facts are arranged in Table II.

In the previous table it has been shown that nitrite may be derived either from protein or from a nitrate and that the cholera-red reaction depends on the simultaneous presence of indole and nitrite in the culture.

From the above table it will be seen that a cholera culture will give a positive cholera-red reaction irrespective of the presence of a nitrate in the peptone water. On the other hand, a *B. coli* culture will show a positive cholera-red reaction only when a nitrate is present in the peptone water but not when it is absent.

That nitrite has an organic source has been mentioned by the authors referred to above, only in connection with the cholera vibrio. The generality of bacteriologists have been wont to take nitrites as derived from a nitrate, notwithstanding the fact that when nitrite is derived from an organic source, it is an oxidation product, while when derived from an inorganic source, e.g., a nitrate, it is a reduction product.

Thus it will be seen that of the three protein reactions referred to in this paper, nitrite as a protein product is the least known, and this fact was well brought out at the time of the discussion that followed the author's referring to nitrite production by *B. pestis*, at the Indian Science Congress held at Madras in 1929.(10)

It has been mentioned above that nitrite occurring in peptone culture has been referred to by a few bacteriologists as one of the substances necessary for the cholera-red reaction. It has not been independently investigated; and the large amount of work done on nitrite as a cultural test in the identification of bacteria refers to the product derived from the reduction of a nitrate. It is in this latter connection that Muir and Ritchie give Ilosvay's reagent for its detection.(5) In short, bacteriologists do not mention any bacillus other than the cholera vibrio as capable of producing nitrite as an oxidation product derived from protein matter.

The late lamented Dr. MacKenzie Wallis, Chemical Pathologist, St. Bartholomew's Hospital, was the first to isolate an intestinal bacillus other than the cholera-vibrio capable of producing nitrite from peptone. This organism was isolated from the faeces of cases of sulph-hæmoglobinæmia(9) and was like *B. alcaligenes* in its carbohydrate reactions. For the detection of nitrite, he used the same reagent, viz., Ilosvay's which is recommended for detecting

nitrites when they happen to be present in a culture as a reduction product. In passing it may be mentioned here that during the course of the study of the faecal flora of the third series of sprue stools, a similar bacillus was isolated by the author, but later this particular case was declared not to be sprue.(11)

The opportunity for studying this third protein reaction, viz., nitrite, occurred when the determination of the purity of plague cultures used in the preparation of Haffkine's prophylactic formed part of the author's routine duties at the Haffkine Institute since 1924.

In the course of a detailed study of cultural reactions it was found that the peptone culture of *B. pestis* responded positively to the Ilosvay test,(7) and being a protein reaction, it was studied with reference to a large variety of bacteria stocked at the Haffkine Institute, with a view to determine its possibilities as a differential character.

Among the intestinal bacilli, no member other than the cholera and cholera-like vibrios were known to be capable of producing nitrite from peptone previous to the nitro-bacillus of MacKenzie Wallis, neither in routine cultural work was nitrite determined except as a reduction product.

In the group of bacteria belonging to hæmorrhagic septicæmia, *B. avisepticus* was found to be capable of producing nitrites, and since it produced indole as well, its peptone cultures necessarily gave a positive cholera-red reaction, a fact that does not appear to have been recorded in the literature; the author was the first one to determine in 1925 the nitrite-producing properties of this organism.

B. pseudotuberculosis, a bacterium liable to be confused with *B. pestis* on account of similar carbohydrate reactions, was found to give a negative response to the Ilosvay test.

B. bovisepicus, a member of the hæmorrhagic septicæmia group of bacilli, was also found incapable of producing nitrite; on the other hand it produced indole and was thus easily differentiable from *B. pestis*.

It will thus be seen that the nitrite test as applied to peptone culture has a great differential value for *B. pestis*, which is incapable of producing hydrogen sulphide or indole. The nitrite reaction in the peptone culture of *B. pestis* has been found to persist for over three months—the longest period observed. In Tables III and IV are given the protein and carbohydrate reactions of the ten strains of fowl cholera in stock at the Haffkine Institute and of the fifteen cultures of the Pasteurella group given by Dr. B. P. B. Naidu, M.D., for determining their cultural characters according to the procedure adopted by the author for *B. pestis*.

In 1925 the author noticed that nitrite had a differential value for *B. pestis* and it will be seen that in this fairly representative variety

of members of the Pasteurella group, there is only one culture, viz., No. 6 which produces only nitrite like *B. pestis*, but unlike the latter grows properly on agar and does not ferment even glucose. Strains Nos. 1 and 16 resemble *B. pestis* in their carbohydrate reactions: of these No. 1 grows properly on agar, while No. 16 behaves like *B. pestis*. Thus of all these organisms Dr. Krishnamurthy's bacillus is the only one which resembles *B. pestis* in its carbohydrate and agar surface characters, but fails in the essential character of nitrite production which it fails to produce in twenty-four hours' incubation as a rule.

It will thus be seen how the cultural tests devised by the author and used alongside with those drawn up by Col. Mackie, assist in an easy differentiation of *B. pestis* from all the members of the Pasteurella group.

Tanaka studied 26 cultures of hæmorrhagic septicæmia organisms from different animals and found a striking similarity in most of the cultural characteristics, in that among other characters all produce indol, ferment sucrose, and reduce nitrates to nitrites. There is no mention of nitrite produced from protein, nor of the cholera-red reaction.

Among the bipolar Gram-negative bacteria that are capable of producing acid in glucose and mannite and no change in lactose and sucrose, are *B. pseudo-tuberculosis* and Dr. Krishnamurti's bovine lymphangitis bacillus. With respect to *B. pseudo-tuberculosis* it has been pointed out above that it is incapable of producing nitrites.

Dr. Krishnamurti's organism is a poor grower in Bactopeptone water and sometimes gives a very faint nitrite reaction, not on 24 hours' incubation at 37°C. as does *B. pestis* invariably, but after 3 or 4 days' incubation. This organism, though resembling *B. pestis* in certain respects, is easy of differentiation therefrom by the protein reaction, and other characters.

I take it that very few bacteriologists would spend time on the serological identity of bacteria that are culturally not identical.

So far an attempt has been made to plead the importance of protein reactions in the identification of species of bacteria. In view of the fact all the four protein reactions can be determined in the same peptone culture, the scheme shown in Chart 1 has been further modified and will be published at length in another place.*

A discovery likely to be of great moment and promise is the differential value of the nitrite reaction in the case of the variants of *B. avisepticus*. For the material which led to this discovery, I am indebted to Major L. A. P. Anderson, I.M.S., Offg. Director, Haffkine

*In order to give an idea how the scheme helps in an easier identification of aerobic bacilli, an abridged form of the revised scheme is shown in Chart 2, Appendix.

Institute,(12) and but for the presence of an accidental contaminant in one of the two variants, and performing the nitrite and cholera-red tests on different days instead of on the same day, this point of difference would have remained unnoticed.

The single culture test for the protein reactions is carried out as follows:—

(1) One per cent. peptone (Bactopeptone) containing 0.5 per cent. salt is tubed in about 4 c.c. quantities in small test tubes and plugged with white absorbent cotton wool.

The Detection of Hydrogen Sulphide.

(2) The culture under investigation is inoculated into the peptone water and the under surface of the cotton wool plug is moistened with a drop or two of 5 per cent. lead acetate solution stocked in small drop bottles. The tube is then kept in the incubator at 37°C.

(3) After overnight incubation, the under surface of the cotton wool plug will be found browned or

blackened if the culture was capable of producing hydrogen sulphide; if not, there will not be any change in the plug.

Detection of Nitrite.

(4) One 5 mm. loopful of the culture is now removed on to a white opal glass plate and a 2 mm. loopful of a freshly prepared Hoesvay's reagent* is mixed in the culture on the plate. If nitrites are produced by the bacterium, the mixed drop will become pink within a minute. If no pink colour develops in two minutes, the reaction is taken as negative.

Detection of Indole.

(5) The rough upper end of the cotton wool plug is smoothed by folding up the rough projections, and

**Hoesvay's Reagent.*—(1) Sulphanilic acid 1 g., Glacial acetic acid 14.7 g., Water 285 c.c. (2) Naphthamine 0.2 g., Glacial acetic acid 14.7 g., Water 325 c.c. These two solutions are stocked in drop bottles. For use an equal number or drops of the two solutions are mixed together in a Wassermann test tube.

then one or two drops of potassium persulphate solution* and one or two of Ehrlich's aldehyde solution† are dropped in succession on the smoothed end of the cotton wool plug, which is then inverted and replaced in the peptone culture tube, so that the newly treated surface faces the culture. The culture is then again put in the incubator for a day. If the bacterium is an indole producer, there will be a pink colour visible on the cotton wool facing the culture. If no pink is to be seen, the bacterium is a non-indol-producer.

If further observations on nitrate production are to be made, the culture is further incubated and tested for nitrite from day to day. After this, the culture is used for determining

The Cholera-red Reaction.

(6) To the peptone culture about one or two drops of strong hydrochloric acid are added. In the case of a positive reaction, a pink colour develops.

on ordinary agar and marked *B. avisepticus* "R" variant.

Since *B. avisepticus* belonged to the Pasteurella group which includes or is allied to *B. pestis*, all the necessary cultural tests detailed by the author in his paper on the "Isolation, Enumeration and Identification of *B. pestis* by Cultivation Methods" (10) were applied to the two variants of *B. avisepticus*.

The first series consisted of liquid cultural tests shown in Table V, while the second series consisted of surface cultivations on different kinds of media the results of which are shown in Table VI.

"	2 days	Plague-like surface growth.	Small yellowish colonies.	About 50 large opaque colonies.	Two sized colonies; a few like those on standard agar.	About 80 colonies, all uniform in appearance.

The two subcultures of *B. avisepticus* referred to above were of the two variants of this bacillus. One was on blood agar and labelled *B. avisepticus* "S" variant, while the other was

Bohme's Solutions.—*(1) Potassium persulphate 1 g.; Distilled water 100 c.c. †(2) Para-dimethyl-amido-benzaldehyde 1 g., Absolute alcohol 95 c.c., Hydrochloric acid 20 c.c. Dilute the resulting solution with an equal quantity of rectified spirit. These two solutions are stocked in drop bottles.

This table shows the results of the sowings of the two variants in the series of liquid media routinely used in the cultural identification of *B. pestis*.

Had these two variants been put up for the determination only of nitrite as required by Major Anderson, it would have been thought that the "S" variant produced nitrite, while the "R" variant did not. However, the carbohydrate reactions threw suspicion on the purity

of the "R" variant culture, since it fermented lactose.

These two subcultures were first planted in broth and subsequently used to inoculate the following media, viz., peptone water, and a set of carbohydrates. A 5 mm. loopful of the broth cultures was also inoculated on acid agar. One 5 mm. loopful of the cultures was diluted in about 10 c.c. of saline and a 5 mm. loopful thereof inoculated on standard agar and on acid agar; a 1 mm. loopful of this dilution was inoculated on blood agar and bile blood agar.

Considering the results of the protein reactions as obtained from the peptone water cultures, it appeared as if there was a cultural difference between the two variants in the facts that while both produced indole and none hydrogen sulphide, the "S" variant differed from the "R" variant in producing nitrites.

However, on reference to the carbohydrate reactions a radical difference was noticed between the two cultures, viz., "S" variant did not ferment lactose, while the "R" variant fermented lactose.

This circumstance brought to the author's mind Weaver's note: "that every one who begins work with a culture which comes to him from any source will first assure himself of its purity and identity, and" of his (i.e., Weaver's) being "in full accord with the statement by Dr. Hall as to the first duties of any author who refers to a living organism by its generic and specific name to make sure by all means at his command of the identity of the form in question."

From Table VI it will be seen that while the 5 mm. loopful of "S" variant dilution planted on standard agar, showed no growth, that from the "R" variant dilution showed small yellowish colonies on the standard agar. These colonies being slightly chromogenic were suspected to be contaminations, and on being examined for their liquid cultural reactions it was found that they responded to none of the protein reactions, but fermented lactose (*vide* Table VII).

The above table represents the results of one of the five yellowish contaminant colonies. They were taken from among those on the

standard agar slope; all the five colonies showed results like the above. (1) All gave negative protein reactions and all fermented the first five carbohydrates with the production of acid. It was thus established that the lactose fermentation seen in the "R" variant in Table V was due to the presence of this contaminant.

It was thus established that the acidity produced in lactose by the "R" variant was due to the presence of a pale yellow contaminant.

The acid agar and bile blood agar slopes showed numerous discrete colonies of both the variants. Six colonies of "S" variant each from the acid agar and the bile blood agar, and three colonies of "R" variant each from the two kinds of slopes as above, were inoculated in peptone water to ascertain their protein reactions and incubated at 37°C. The next day, i.e., on one day's incubation, all the peptone cultures were found to be negative to the hydrogen sulphide test but positive to the nitrite test. After two days' incubation the indole reactions were read and found to be positive for all the eighteen colonies. The cholera-red test was then applied to all the cultures and to one's surprise it was found that while all the twelve peptone cultures of the "S" variant colonies responded positively, all the six "R" variant cultures gave a negative cholera-red reaction (*see* Table VIII, Section A).

It is well known that the cholera-red reaction when tested for on a peptone culture depends on the simultaneous presence of indol and nitrites, both these products being obtained from the peptone as a result of the bacterial action.

It was therefore surmised that the failure of the "R" variant peptone cultures to respond positively to the cholera-red reaction might have been due to some discrepancy with respect to nitrites. Nitrite was tested for after 24 hours' incubation and not tested for again after 48 hours' incubation when the indole tests were read and the cholera-test carried out. A circumstance to explain this phenomena is the probable disappearance of nitrite on 48 hours' incubation of the "R" variant culture.

In order to substantiate the above surmise, six fresh colonies of each of the two variants

were planted in peptone water and the resulting cultures were tested after one, two, and three days' incubation for indole, nitrites and the cholera-red reaction. The results obtained are given in Table VIII (Sections B and C).

After one day's incubation all the twelve cultures were tested for nitrite and indole and one of each kind tested for the cholera-red as well. After two days' incubation one culture of each variant was tested for the three reactions; and lastly the remaining four cultures of each kind were similarly tested after three days' incubation.

From this table it will be seen that, except for one culture out of the six, of the "S" variant all gave a positive indole, nitrite and the cholera-red reaction, even when the latter reaction was determined on three days' incubation in respect of the four cultures.

On the other hand out of the five colonies of the "R" variant examined on two and three days' incubation only one gave a positive cholera-red reaction, though all showed nitrite and indole on one day's incubation.

These results confirmed the surmise that while the "S" variant was capable of showing a positive nitrite reaction even when tested for on the fourth day of incubation, the "R" variant cultures contained nitrites 24 hours after incubation but not after 48 hours. Accordingly bacillus "S" variant would give a positive reaction after a fairly long period

the "R" variant would show it only after a long incubation and rarely after 48 hours.

Bohme's Solution
1 g.; Distilled water 100 c.c.
amido-benzaldehyde 1 g., Absolute alc.
Hydrochloric acid 20 c.c. Dilute the resulting became with an equal quantity of rectified spirit. These solutions are stocked in drop bottles.

it is interesting to note that among the four "R" variant colonies that were tested for the cholera-red reaction on the fourth day of incubation, there was one colony which resembled the "S" variant colony in its protein reaction. The presence of such a colony among the "R" variant colonies as examined by means of the protein reactions raises the question whether the colony referred to may not be of an intermediate type.

In order further to confirm the above findings, viz., that while the "S" variant shows a positive nitrite reaction for a fairly long period, and the "R" variant shows it only for a much shorter period of incubation, a large number of colonies from the "S" variant and the "R" variant slopes were put up in peptone water and the resulting cultures tested for the protein reactions after varying periods of incubation. The results as obtained are shown in Table IX.

From this table, Section A, it will be seen

- (1) That all the 68 colonies of the "S" variant continued to respond positively to the nitrite test beyond three days' incubation.
- (2) That out of 72 colonies of the "R" variant five failed to respond to the nitrite even after one day's incubation.
- (3) That out of 67 colonies of the "R" variant 12 responded positively after two days' incubation, and
- (4) That out of 6 colonies 1 responded positively on three days' incubation.

In Section (C) are given the details of variations in the periods of response to the nitrite test shown by a number of the "R" colonies.

Discussion.

It has been shown that in one culture all the four protein tests can be carried out, thus immensely facilitating the examination of a large number of cultures.

Of all these tests, indole is the most commonly used one, then comes the hydrogen sulphide test, and lastly the cholera-red reaction.

However, it is to be noted that the cholera-red test has been used in the case of the cholera and cholera-like vibrios only.

Whenever there is a mention of nitrite, it is generally understood to be derived from a nitrate present in the medium either on purpose or as an impurity. It is only a very few authors of textbooks on bacteriology who have made a clear mention of the fact that nitrite is derived from a protein substance as well, e.g., peptone of the culture medium; and this is mentioned only with reference to the cholera or cholera-like vibrio.

Dr. MacKenzie Wallis was the first to point out the presence of a bacillus other than the cholera vibrio, capable of producing nitrite from peptone, its presence in the culture being determined by means of the same reagent, viz., Ilosvay's, used in the detection of nitrites when produced from a nitrate.

The nitrite produced from a nitrate—an inorganic source—is a product of reduction, while the nitrite produced from a peptone—an organic source—is a product of oxidation.

Except MacKenzie Wallis' bacillus which resembles *B. alcaligenes* in its carbohydrate and staining reactions, there is no other bacillus which has been mentioned in the literature as a nitrite producer—of course barring the cholera and cholera-like vibrios.

Thus whenever Ilosvay's reagent is used for determining the presence of nitrite, it is a test for it as a reduction product and not as an oxidation one.

It was in the course of a detailed study of the cultural reactions of *B. pestis* that the writer found this bacterium to be a nitrite producer.

This finding, being a protein reaction, served as a valuable supplement in the system of control tests introduced by Col. Mackie for determining the purity of plague cultures used in the manufacture of Haffkine's prophylactic.

Since this important finding and absence of its mention in the literature except with reference to the two organisms mentioned above, the nitrite test was applied to the peptone cultures of a large variety of bacilli. As a result it was found that *B. diphtherie* and *B. avisepticus* were among nitrite producers, while *B. pseudo-tuberculosis*, a bipolar bacillus generally confounded with *B. pestis* owing to similarity in their carbohydrate reactions, was incapable of producing nitrite in its peptone culture. *B. bovissepticus*, another member of the Pasteurella group of bacilli, does not produce nitrite, but is capable of producing indol.

B. pestis is capable of producing nitrite, as is also *B. avisepticus*; however, the latter produces indol, while the former does not. Both these organisms are incapable of producing hydrogen sulphide.

These three protein reactions have now been introduced in the classification of bacteria which has been further modified as will be seen from the three culture method detailed anew in another place.

So far no biochemical reaction has been described by means of which variants of a species of a bacillus could be differentiated.

It is, therefore, interesting, to point out here that in the nitrite test a differentiating character has been found by means of which the two variants, viz., the "S" and "R" variants of *B. avisepticus* could be differentiated.

Major Anderson recently completed a study "On the Dissociation of *B. avisepticus*" and gave the author two subcultures—one of the "S" variant and the other of the "R" variant of this bacillus for the determination of their nitrite character.

Since *B. avisepticus* belongs to the same group of bacilli as *B. pestis*, the two subcultures were put up for the routine tests used by the author for the cultural identification of *B. pestis*. As the result of two accidental circumstances in the course of this investigation, a discovery has been made which may be of value in the purification of certain cultures intended for biological tests—serological and virulence.

The first circumstance was the detection of a contaminant in the "R" variant culture, and the second was the carrying out of the tests for nitrite and cholera-red on different days. The first led to a detailed study of several colonies resulting in the finding of mixed types, and the second to a differential value in the length of the period of response to the nitrite test.

The "S" variant colonies of *B. avisepticus* all responded positively to the nitrite test over a fairly long period of incubation, while the response of the "R" variant colonies lasted for a much shorter period in a majority; in the case of a few colonies there was no response to nitrite.

Thus in the nitrite test there has been discovered not only a protein biochemical character to distinguish the "S" from the "R" variant of *B. avisepticus*, but a possible criterion by means of which the course of dissociation of a soft culture may be followed up with greater precision than by means of the tests used at present; and thus a more uniform culture for biological tests may be obtained than otherwise.

It would thus appear that of the two protein characters of *B. avisepticus*, the nitrite character has been shown to be labile. It would be interesting to see whether the indol character could be similarly obliterated and what effect it would have on the *in vivo* tests.

The phenomena observed above, viz., the disappearance of the nitrite reaction in the peptone culture of a rough variant of *B. avisepticus*, has not so far been noticed by the author in the case of *B. pestis*; the number of individual colonies submitted to this test being not less than some hundreds.

If a test tube reaction could be found to correlate with virulence it may facilitate routine work connected with the manufacture of vaccines and sera on a large scale.

The nitrite producing bacteria contain as observed above, *B. pestis* and some other members of the hæmorrhagic septicæmia group of bacilli. It also contains *B. diphtheriæ*, thus altogether the nitrite forming character of these bacilli is worth an intensive and intelligent study.

If such a study is found fruitful, hydrogen sulphide and indole production of bacteria may be taken up for a similar investigation.

The hydrogen sulphide producing bacteria include *B. typhosus*, *B. paratyphosus* B and C, *B. enteritidis* and other food poisoning group bacilli. The classification of these bacilli demands a quantitative study of this character. So far it has only been partially studied and that too only qualitatively.

Further knowledge on a subject could only be gained by a quantitative study and the three long known protein reactions referred to in this paper await such a study.

The indole character, though associated mostly with commensals, includes the Flexner and other dysentery bacilli, such as the *meta-dysentericus*. Among these types there are strains which are not capable of producing indols. There is little information available regarding the difference in the virulence of indoligenous and anindoligenous strains, as manifested either in human cases or in experimental animals.

It is known that Shiga's dysentery bacillus which is a non-indol-producer is more virulent than Flexner's. So is *B. paratyphosus* A a fever severer in type than that caused by *B. columbiensis*. The cultural difference between these latter two organisms is their indolic character; the former is incapable of producing indole while the latter is not.

Many other instances could be cited in support of the case made out in this paper for an intensive and intelligent study of the protein characters of bacteria, and nowhere is there a greater opportunity for the co-operation of bacteriologists and chemists than in a subject like the one under review.

Dr. Gilbert Fowler writes: "Prof. Donan in his stimulating British Association address on the mystery of life advocated the study of the biochemistry of unicellular organisms as the shortest path to the solution of many fundamental problems."

Prof. J. F. Thorpe says "...too little is being done to approach the problems from the purely organic chemical side, and too few of the people engaged in biochemical research have an adequate knowledge of organic chemistry or the method of the organic chemist. The number of organic chemists who are co-operating with biologists in their attack on natural processes is too few."

The few and minor observations that the author has been able to record in this paper are the result of the opportunity he had in the

giving the results of biological tests more concordant than as at present.

In fine, in the history of cultural reactions, it is for the first time that a protein reaction, viz., nitrite production, has been shown to correlate with virulence.

A CASE OF FULL TERM ABDOMINAL PREGNANCY: LIVING MOTHER AND CHILD.

By A. H. DRIVER, M.B., Ch.B.,
London Mission Hospital, Jammalamadugu, Madras Presidency.

On 21st January, 1930, there came into hospital from a distant village a woman whose condition

course of his routine duties in connection with the investigation first of water bacteria, then of faecal bacilli, and lastly of the plague bacillus. No observation has been put forward in this paper that was not the result of personal work.

If further work on the lines suggested in this paper is found to be in conformity with the present work, other protein reactions may be similarly made use of in studying the variants of respective species.

Summary.

1. That the value of the four long known protein reactions—viz., hydrogen sulphide, indole, nitrite and cholera-red—is an easier and more definite mode of identification of bacteria than by means of carbohydrate reactions alone, has been shown in previous studies.

2. The routine testing of these products has been greatly facilitated by the introduction of a method by means of which the presence or absence of all these products can be ascertained in the same liquid culture.

3. The conjecture made by the author that a correlation between *in vitro* and *in vivo* reactions is more likely with protein than with carbohydrate reactions has found a proof in the nitrite test, which has been shown to distinguish the "S" variant of *B. avisepticus* from its "R" variant.

4. In the nitrite reaction, a characteristic of some of the important member of the Pasteurella group of bacilli and of *B. diphtheriae*, there is a promise not only of differentiating the variants of a species, but of anticipating their pathogenicity and serological behaviour.

5. Lastly, it may not be extravagant to hope that what has been found to be true in the case of one protein reaction, may also be found of value in the case of the other protein reactions.

Conclusion.

It has been shown in this paper that by means of the single procedure devised by the author for the determination of the four protein characters, viz., hydrogen sulphide, indole, nitrite and cholera-red, not only can certain species of bacteria be more easily differentiated than by means of the carbohydrate reactions alone, but also the variants of a species *B. avisepticus*—can be distinguished and the degree of dissociation can probably be measured, rendering the results of biological tests more concordant than as at present.

In fine, in the history of cultural reactions, it is for the first time that a protein reaction, viz., nitrite production, has been shown to correlate with virulence.

NOTES ON CHART 2.

1. Discrete colonies are obtained from the material under examination by sowing its serial dilution on agar and superimposed blood agar slopes.

2. Type colonies are cultivated in peptone water and purity established by planting the peptone culture on agar and superimposed blood agar slopes.

3. Each type of colony is then sown in (i) glucose broth, (ii) litmus lactose peptone water and in (iii) bacto-peptone water. The positive reactions in these media give the formulae for the cultures.

4. Reference to the source of the bacillus, the differential growth on agar and blood agar, Gram stain and motility indicate the probable species of the bacillus.

5. Confirmatory tests finally define the species.

Remark.—Believing that it is not enough to arrive at a classification, which after all is merely an aid to description, in the last four columns of Chart 2 are shown the results obtained with respect to the aerobic faecal bacilli in health and disease.

A Mirror of Hospital Practice.

A CASE OF FULL TERM ABDOMINAL PREGNANCY: LIVING MOTHER AND CHILD.

By A. H. DRIVER, M.B., CH.B.,
London Mission Hospital, Jammalamadugu, Madras
Presidency.

ON 21st January, 1930, there came into hospital from a distant village a woman whose condition

exemplified one of those curiosities of medicine whose occurrence enliven the routine of a mofussil hospital. She had been having "labour pains" for four or five days, of considerable intensity, her last confinement, the first, having taken place seven years ago. On examination a child's head could be clearly made out just below the umbilicus, and apparently just beneath the abdominal wall. Occasional movement and bulging in the right flank suggested a free limb. The os was soft and normal in position, but quite undilated. Fœtal heart sounds were clear. She gave a history of uninterrupted amenorrhœa for eight months prior to admission. Suspecting an extra-uterine gestation I urged an immediate abdominal section but as the "pains" subsided considerably this was refused until the third day after admission when recurrence of pain made patient and relatives submit to my persuasive efforts. On 23rd January afternoon, under chloroform-ether, with the assistance of Mr. J. R. Sampson, L.M.R., I made the usual Cesarean incision, and immediately under the peritoneum was a thickened fœtal sac which was incised and from which was extracted, head first, a living male child weighing 6½ lbs. The sac contained a little grumous fluid, and was attached firmly to loops of small gut which prolapsed freely into it. The placenta was bipartite and about double the normal size. Of its two sections the major portion, three times the size of the minor, was perched on the top of the fundus of the uterus completely concealing that organ from view. At its centre it was densely attached to the peritoneum covering the fundus. The minor section of placenta was unattached, filling up the right pelvis. The uterus itself was little more than normal in size. To release the main placenta I had to cut horizontally through the fundus, controlling the brisk bleeding by ligatures and mattress sutures. Ovary and tube on the right side appeared to be normal in size and position. Ovary and tube on the left side were adherent to the wall of the sac, but the tube showed no sign of sacculation or of previous rupture, and the ovary showed no abnormality. I noticed no sacculation at one cornu of the uterus that might have suggested an interstitial pregnancy. As much of the sac as could be safely removed was cut away along the bowel margin. The peritoneum was washed with saline and intravenous saline given. The mother made an uneventful recovery and was suckling her infant on the fourth day.

Cases of this nature are rarely seen outside large maternity hospitals. Their incidence is about 1 in 13,000 confinements, Lient.-Col. Green-Armytage informs me. Probably cases in which both child and mother survive, and the former is free from deformity, are rarer still. The extraordinary position of the placenta seems to me to be one of the most striking features of this case.

A NOTE ON THE LOCAL TREATMENT OF LEPROUS ULCERS.

By MILTON C. LANG, M.D.,

Hotel Chamossaire, Leysin Suisse, Switzerland.

ON taking up the work at the Chandkuri Leper Homes the writer found that the trophic ulcers—which, like the poor, were always with us—were being treated with an appalling array of remedies. In fact, every plausible application in the Pharmacopœia was used and these were amply supplemented by numerous home remedies, such as cow-dung, ashes, and poultices of various leaves, by the patients themselves.

Naturally our results from the treatment of this condition were poor and we at once elimi-

nated most of what appeared to be superfluous and useless drugs. Among them was iodoform which had been used in large quantities as a powder applied to the ulcers; thus, much was wasted. When the patients could no longer obtain *pila dewai* they became very dissatisfied and complained bitterly, saying that this, of all drugs, helped to relieve the pain which was caused by the ulcers in some cases.

In an institution of this type where other than gentle force is out of the question, it is very essential to keep the patients in a cheerful frame of mind, and at this time it seemed that the only thing that would do it was iodoform. Yet the expense had to be considered also. The point was, how to use iodoform effectively but not in a wasteful manner?

At first I attributed its effect largely to the psychological elements of colour and smell, but after having followed numbers of cases treated with it and others treated with different applications, I was convinced of its superiority both as to its powers to clear up infected cases and as to its analgesic effects.

I found that by using the drug in solution even better results could be obtained at a fraction of the cost. Two solutions are in use, one in acetone, and the other in eucalyptus oil. The former we use for the ordinary small and often painful ulcer, and the other for the large necrotic, sloughing types which if not carefully treated would rapidly lead to gangrene. The solutions are made as follows:—

(a) 16 grains of iodoform to the ounce of acetone.

(b) A 10 per cent. solution in eucalyptus oil.

At first we had difficulty in convincing our patients that we were using iodoform, but, when we swabbed an arm or two with the acetone solution and after a moment or two the acetone evaporated and left a yellow streak of iodoform plainly visible, there was no further trouble.

In using the solutions one is assured that the drug reaches all parts of the ulcer. It is perhaps needless to say that the ulcers must be otherwise properly cared for; dead or hardened flesh trimmed away, an indolent base transformed into a healthy granulating one by the judicious use of silver nitrate stick or the curette, sinuses opened up freely, and dead bone removed. The ordinary types are dressed every other day, but the sloughing varieties are dressed daily with cotton soaked in the eucalyptus oil solution which is tightly packed into the ulcer. This is done by a skilled dresser under the supervision of a medical attendant, who is able to judge if any more active intervention is necessary.

If it were possible properly to apply rest, careful exposure of the ulcers to the sun's rays, and real aseptic treatment to all our cases, this would without doubt be ideal, but in dealing with *jungly log* for the most part we must

do the best possible under the circumstances, and in our hands this method has given by far the best results.

AN EASILY IMPROVISED APPARATUS FOR THE TREATMENT OF FRACTURE OF THE FEMUR.

By R. C. McWATTERS, M.B. (Lond.), F.R.C.S. (Eng.),
LIEUTENANT-COLONEL, I.M.S.,
Principal, Medical School, Agra.

THOSE whose duty it is to inspect village dispensaries are often shocked to find cases of fracture of the femur being treated on Liston's splint, none too well applied, with two or more inches of shortening and some rotation outwards of the foot. In district hospitals these cases are often treated with a Thomas' knee splint many sizes too large and the results are often lamentable.

Where suitable apparatus is not at hand fractures below the upper third may be efficiently treated with an apparatus which may be made in any village.

Take an ordinary lathi and tie it to the two legs of the foot of the bed, near the lower ends (Fig. 1). Take a board 4 inches wide, about two inches longer than the height of the bed, and about 1 inch thick. With the help of a carpenter cut a notch in the upper end and drill a hole from side to side as in Fig. 2. An empty cotton-reel is then fixed in the notch by passing a long round nail through the holes in the board and in the reel: this makes an efficient pulley.

The board is now tied to the foot of the bed and to the lathi as in Fig. 1.

The limb is then fixed in the usual plaster strapping extension and the cord is carried over

Fig. 1.

board further out towards the leg of the bed. Rotation of the limb is prevented as follows:

Wrap the ankle in cotton-wool. Place a thin board 3 inches wide and 12 inches long behind it, and at right angles to the leg; then fix it to the ankle by means of a plaster-of-Paris bandage applied in a figure of 8 around the board and the ankle. In hot weather an ordi-

Fig. 2.

nary bandage may be used reinforced with a few turns of adhesive strapping.

It is not claimed that this is the best method. But it can be carried out anywhere, it is much better than an ill fitting splint and requires less skill to manage than more complicated methods. Shortening of the limb is exceptional and the chief objection is that painful disturbance of the fracture occurs when the bed pan is given. If the patient is restless a long Liston's splint is applied to the sound side.

The method was in general use before the introduction of Jones' and similar splints, except that it was carried out by means of special pulleys not obtainable in remote dispensaries.

CHOLERA AND MALARIA.

By KARTIK CHANDRA BANERJEE,
P. O. Chandijan (Durgapur), Rangpur.

THE treatment of malaria is very easy, but its diagnosis is frequently quite difficult without a microscope, as the complex clinical symptoms often puzzle the most judicious practitioner. Dr. Manson-Bahr remarks in his *Manual of Tropical Medicine*—"the use of the microscope must not be neglected in such cases if there be the slightest doubt as to their exact nature."

the pulley and attached to a weight of 4 to 12 lbs. according to the muscular development. Two bricks are placed under each leg of the bed at the lower end so that the patient may not be dragged down by the weight. Abduction, if required, may be obtained by fixing the

Again he says... "without the microscope its true nature may be hard to recognise." In June 1926, I too expressed a similar opinion in the *Indian Medical Gazette*,—"If the disease is properly diagnosed its treatment is usually straightforward, if otherwise, in the majority of the cases the results are bad." Differential diagnosis must depend solely upon the careful examination of stained blood films and in doubtful or confused cases this must be persisted in. The above will be justified by the following statement.

On 13th December, 1929, during the last cholera epidemic, I had to attend a female patient, said to have been attacked with cholera, and observed the following symptoms:—

Bile-tinged watery motions, extreme prostration, pulse thready and feeble, respiration laboured, intense thirst, tongue dry and coated, temperature 95°F., heart beats tic tac, spleen just palpable, urine suppressed for about 6 hours, liver and lungs normal, senses intact.

I took it to be a case of cholera yet in order to arrive at a definite diagnosis, (1) some excreta was at once collected in a sterile wide-mouthed bottle, (2) peripheral blood films were taken on two slides, and the following was prescribed.

Subcutaneous injection of:—

(i) Adrenaline chloride sol. 1 : 1000, 1 c.c.

(ii) Atropia sulph. gr. 1/100 in 1 c.c. distilled water were given alternately.

For oral administration:—

(i) Essential oils mixture, 4 doses to be taken every hour.

(ii) An alkaline mixture, 4 doses to be taken every 2 hours.

On returning to the laboratory the specimens were examined microscopically. The stool was negative for cholera vibrios, while innumerable malignant tertian parasites were seen in the blood film. Meanwhile I was again called in and found her condition still worse. Cramps of the muscles and extremities, profuse clammy sweat, restlessness, griping pain in the abdomen, voice sunk to a whisper, were the new troubles set in. Accordingly an intravenous injection of quinine bi-hydrochloride gr. X, in one pint of normal saline was given.

After a short while the temperature rose to 103°F.: this was accompanied by shivering, which of course ultimately subsided and in the course of an hour or so the pernicious symptoms exhibited a favourable turn (i.e., were of less severity). Four doses of quinine mixture were given orally every 3 hours.

On the 14th December, she was reported to be all right in all respects. Turbid urine was secreted at night, and the only complaint was headache and weakness. Four doses of quinine mixture, containing liquor arsenicalis and strychnine, were given, and milk for the diet.

On the 15th December, she had no complaint. Medicine and diet were given as on the 14th. On the next day she was all right, and allowed to have her usual diet. A mixture containing quinine, iron, and strychnine, and a bottle of cod-liver oil were prescribed, to be continued for at least a month. She regained her former health.

SOME CASES OF SURGERY OF THE HAND.*

By R. C. McWATTERS, M.B. (Lond.), F.R.C.S. (Eng.),
LIEUTENANT-COLONEL, I.M.S.,

Principal, Medical School, Agra.

Case 1.—A young man received a bullet wound of the hand which penetrated the palm and fractured

the middle metacarpal. Some months later the extensor tendon was firmly attached to the bone so that the finger could not be flexed.

In such cases it is useless merely to free the tendon as the adhesions invariably form again. The following operation was therefore performed. A large flap incision was made so that the sutures should be well away from the affected area as a precaution against sepsis. The tendon was dissected away from the bone and a thin layer of fat derived from the thigh was placed beneath it, after breaking down some adhesions in the joints of the finger. After a week passive movements were begun and were gradually increased. The final result was almost full range of movement, the limitation that remained being due to adhesions in the metacarpophalangeal joint and no greater than was present at the time of operation.

The pad of fat in such cases adheres to both structures, but in time the fat is absorbed and is converted into lax tissue which allows of free movement.

There is no novelty in the method; it is described here because it is easy and almost universally successful and deserves to be more widely used than it is.

To avoid infection of the graft it is necessary to wait for several months after the original wound has healed, to keep the skin wound well away from the region of the graft and to avoid touching the parts with the hands, everything being done with forceps and other instruments.

Case 2.—In a lathi fight an elderly man received a fracture of the ulna and a severe contusion of the back of the hand. The fracture had been skillfully treated and had united well, but the fingers were quite stiff owing to widespread adhesions of the extensors. These were considered to be too extensive for treatment as above, so a malleable splint was made of thin sheet iron and by gradually bending it the fingers were slowly flexed. In the course of a few weeks a fair degree of flexion was obtained, but the result was by no means perfect.

I have seen several similar cases and the moral is that in severe contusions of the hand the existence of other injuries must never interfere with early passive movement of the fingers—otherwise the contusion will prove far more grave in its results than the associated fractures, though only the latter are at the time regarded as "grievous hurt." Being medico-legal cases, such patients make the most of their disability and give no assistance, and it requires some resolution and much assiduity on the part of the surgeon to secure a good result.

Case 3.—A European schoolboy developed a severe whitlow of the thumb. When this was opened up it was found that both phalanges were necrosed. The further treatment involved some interesting problems. With the loss of the bone the thumb would become a useless soft lump of flesh. In spite of free drainage the discharge remained profuse and pain and some fever continued. Amputation would have cut this short, but the boy was anxious to enter government service from which he would have been debarred by the loss of a thumb.

It was decided to treat the case just as one of necrosis of the femur. The dead bone was left in place to maintain the shape of the thumb in the hope that an involucrum of new bone would form. Regeneration of bone in the fingers is notoriously feeble, and I was unable to obtain any information as to whether it might be expected in such a case as this, but the youth of the patient was in his favour.

In two months' time regeneration was excellent and the sequestra were removed.

The basal epiphysis of the proximal phalanx had escaped, and with it the metacarpophalangeal joint—the interphalangeal joint was of course lost.

Healing was rapid and the boy has an ugly but very useful thumb with a fair range of movement at its base. He has since gained admission into government service.

(*Being part of a clinical lecture delivered at the Agra Medical School.)

Indian Medical Gazette.

MAY.

PSITTACOSIS.

THE disease known as psittacosis has always been one of the curiosities of medicine, but the present widespread incidence of the disease in countries as remote from one another as South America, the United States, Germany, Switzerland, and Great Britain has naturally aroused the attention of both the medical and lay press. Psittacosis is defined by Dorland as a contagious influenza-like disease of parrots, communicable to man, and characterized in man by a typhoid- or paratyphoid-like disease associated with severe pulmonary symptoms and high fever. The literature in the medical journals for 1929-30 is already so extensive that it is difficult to summarize it, but as cases may have occurred or may be occurring in India, we may draw attention to it. The parrot has always been notorious for its language; its morals have always been under suspicion; it is now somewhat unfortunate for this domestic pet that it should also come under suspicion as a transmitter of disease to man.

Psittacosis as a separate clinical entity first appears to have been defined by Ritter in Switzerland in 1879, who drew attention to an apparent connection between small epidemics of pneumonia limited to certain houses, and an illness among parrots in the same houses. According to Castellani and Chalmers, a severe outbreak occurred in Paris in 1892; 500 parrots had been shipped from South America to Paris, and 300 of them died en route from enteritis. The remainder were sold in Paris, with the result that within 26 days an epidemic of the human type of the disease broke out, resulting in 49 cases with 16 deaths. The epidemic was characterized by being essentially a house disease. Smaller epidemics were reported in Paris in 1893, Florence in 1894, in Cologne and Paris in 1895, Genoa in 1897, in 1901 at Ancona and Hull, in 1904 in New Hampshire, U. S. A., in the same year in Boston, U. S. A., whilst small series of cases or isolated cases have been subsequently reported from time to time in the literature. In 1892 Nocard of Paris isolated a bacillus—the *Bacillus psittacosis*—from both avian and human cases of the disease, closely related to the *Bacillus paratyphosus* B. It was subsequently shown that this bacillus was probably identical with the *Bacillus aertrycke*.

In the parrot the disease is essentially one of septicæmic type—often of hæmorrhagic type—with marked catarrhal symptoms and enteritis,

and is usually fatal. In man the disease almost invariably follows association with sick parrots, parakeets, love birds, or finches after an incubation period of some 7 to 12—usually 10—days. The disease resembles typhoid or paratyphoid fever, but the onset is more sudden, with chill, high fever at an early stage, sometimes cervical rigidity, occipital headache, and coma. Epistaxis, rose spots, abdominal distension, and sometimes diarrhœa, are mentioned as complications. The most important feature of the disease in man, however, is its involvement of the lungs; this may commence as a "shifting bronchitis," but may go on to broncho-pneumonia, or to consolidation of large areas of the lungs. Convalescence is by lysis, and it is characteristic that the patients take a long time to recover normal health.

It is a little difficult to trace the origin of the present widespread outbreak. Taking the papers as they appeared in historical sequence, the first case recorded appears to have been the one reported by Dr. A. P. Thomson, which occurred in Warwick in July 1928. Enquiries showed that the patient, a middle aged Englishwoman, had purchased a parrot some weeks before her illness, and that the parrot had become ill and had died whilst being nursed by the patient; this bird was one of a consignment from West Africa, a large number of whom had succumbed to "parrot disease" after importation into Great Britain. In the same paper, the author records two further cases which occurred at a nursing home, associated with nursing a sick parrot; one of these proved fatal from pneumonia. A third nursing sister at the home had an unusual and very protracted attack of febrile bronchitis; these cases occurred between November 1928 and February 1929. It is noted that vomiting is frequently an early symptom of the disease, and delirium may be severe.

The main focus of the present outbreak, however, appears to have been the Argentine Republic (and it is curious to note that nearly all previous epidemics have been traced to sick birds imported from South America). About July 1929 an epidemic of what was taken to be epidemic influenza occurred at Cordoba, and Dr. Henry Barros showed its special association with a fatal epidemic among birds, especially cockatoos, most of which had been recently imported into the city. Within a few days the epidemic had spread to the neighbouring town of Alta Gracia; later it became widely prevalent in the city of Tucuman. In August-September 1929 it invaded Buenos Ayres, and hundreds of cases were reported. In October a party of actors was attacked, the death of a parrot which had taken the part of a sailor's pet in a play being responsible; there were 9 human cases with 2 deaths. Full clinical accounts of the disease as studied in man are given in *El Dia Medico* for the 23rd and 30th September, 1929,

by Dr. Henry Barros. Two special Commissions were appointed to study the disease, one by the Tucuman Hygienic Council in September 1929, and the other by the Argentine Medical Association.

From this focus the disease spread very widely in the autumn and later months of 1929. The S.S. *Arkona* arrived in Germany in November from South America and her cargo of parrots was distributed to Hamburg and Berlin. A considerable number of cases of psittacosis followed in both cities, with some deaths. In the meantime cases and some deaths were reported in January 1930 from Baltimore, New York, Maryland, and Ohio in the United States. In all instances it was established that the victims had recently purchased or handled parrots which were ill and soon died. In January 1930 Dr. J. S. Warrack described a case; the patient was a ship's carpenter who was landed sick at Gravesend on December 9th, 1929, from a ship from Buenos Ayres. He had purchased two parrots there and kept them in his cabin; both had died during the voyage. The serological findings were negative to the enteric group of bacilli, as well as to *B. psittacosis* and *B. artrycke* in all dilutions. No other cases occurred on board the same ship.

The bacteriological workers at the London Hospital now took up the study of the disease, and at a meeting of the Section of Medicine of the Royal Society of Medicine on January 28th, 1930, Dr. A. P. Thomson of Birmingham read a paper on the disease. He stated that since July 1928 he had seen 17 cases, of which 5 had proved fatal; all had followed the handling of sick parrots. Cheshire, Worcestershire and Warwickshire were the counties chiefly affected. In some cases, as the temperature fell by lysis, the patient's condition became worse and not better. The physical signs in the lungs might not clear up until the tenth day after the temperature had become normal. An interesting case was that of a Jewish girl who, according to Jewish custom, had been presented with two love birds on her betrothal. One of these birds was ill, and the girl developed psittacosis with severe consolidation of the lungs and a temperature of 104° to 105°F. for eight days. He recorded a fatal case in 1926 in a patient who had brought three parrots to England from West Africa, all of which had sickened and died of diarrhoea. A full clinical account of the disease is given in this most interesting report, and it is noted that the pulse is relatively slow, as in enteric fever; epistaxis may occur, sweating may be severe in the early stages, cough is frequent but not painful, expectoration is scanty or absent. Respiration is not hurried unless the extent of lung tissue involved is extensive. Agglutination to the *B. psittacosis* and the *Salmonella* group of bacteria is frequently absent, or, if positive, is frequently only transient. Dr. Robert Hutchi-

son of the London Hospital had seen 20 cases, of which 2 had proved fatal. The parrots concerned were nearly always green parrots. He had only rarely seen the dense consolidation of the lungs described by Dr. Thomson. Several other speakers took part in the discussion, and Dr. Western of the Bacteriological Department of the London Hospital reported that in 12 human cases and 6 infected parrots he had been unable to find any evidence of infection with any organism of the *Salmonella* group. By this time Germany had issued regulations prohibiting the importation of parrots into that country; the United States shortly afterwards took the same precaution.

In the *Lancet* of February 1st, 1930, Drs. S. P. Pedson, G. T. Western, and S. L. Simpson submitted a report from the Bacteriological Department of the London Hospital; they had been unable to obtain any bacteriological or serological evidence of infection with any organism of the *Salmonella* group, and had come to the conclusion that the disease was due to a filterable virus. Parrot tissues were still infective after being kept for 20 days in 50 per cent. glycerol in the cold. In the meantime other observers had reported that the faeces of infected parrots are infective, as also the dead birds, which should on no account be handled; and that the incubation period in imported parrots might be very prolonged. The virus will pass through a Chamberland LI filter.

In an editorial comment in February 1930, the *British Medical Journal* drew attention to the disease, but noted that there were no grounds for apprehension; also that the London Zoological Gardens had remained entirely free from infection. In the same month the *Lancet* gave an account of the outbreak in Germany; two small outbreaks had involved three members of a family which traded in imported animals, and the other the staff and patients of the St. Gorg Hospital in Hamburg. There were 9 cases in these two outbreaks. Fourteen cases had occurred at Barmbeck. A third outbreak occurred in a household in Berlin, a member of which had brought back four birds from the Upper Amazon, three of which became ill; there were 2 deaths and 3 recoveries in this household. Still another small outbreak affected six persons who had come into contact with a sick parrot. The bacteriological findings had been completely negative, and the German, equally with the British, investigators considered that they were dealing with a filterable virus, and that the *B. psittacosis* was not the aetiological agent of the disease.

In the *Medical Clinics of South America* in January 1930, Dr. J. Sailer described a further case which occurred in Pennsylvania. He notes that the sick parrots crave water to drink incessantly, that they suffer from severe diarrhoea, will not eat, and droop. The feathers are ruffled and easily fall out. A parrot which has

apparently recovered from the disease may suffer from a relapse. In man there is leucocytosis, and the urine may show albumin and pus cells. Blood agglutinations were negative, and no organisms of the enteric group could be recovered from the faeces. Cocaine and adrenalin applied to the nasal mucosa relieve the distressing headache, whilst ammonium chloride should be given orally.

The second bacteriological report by Drs. Bedson, Western, and Simpson was published in the *Lancet* for February 15th, 1930. It confirms fully that the virus of the disease is a filter-passing organism. In only one bird out of six examined was the *B. ærtrycke* isolated, and here the lesions present at post-mortem examination were entirely different from those in psittacosis. Eight budgerigars inoculated with citrated blood from human cases all became infected, and from two of them filtrates of suspensions of the liver and intestine proved infective. The epidemiological evidence tended to some extent to show person-to-person infection without the intermediary transmission by birds. A human case occurred from the bite of a parrot which had been ill eleven months previously, had recovered, and had shown no symptoms at all except for occasional attacks of diarrhoea in the interval. Pigeons and guinea-pigs proved resistant to the virus, but fowls are susceptible, and the question of the relationship of psittacosis to "fowl plague"—which is also due to a filterable virus—is raised.

In February 1930 Dr. Mary Radford contributed a detailed clinical account of a further outbreak in a family at Oxford. The two sons of Dr. and Mrs. M. imported a green parrot on December 21st, 1929, which arrived ill on a very cold day, and died on December 30th. In all 8 persons were more or less in contact with this bird, and 5 became infected. This paper contains temperature charts of the disease and much clinical information with regard to it; the illness was severe in all cases; two patients showed a clinical picture very suggestive of typhoid fever, and three had lung complications, but in no case was there the solid condition of the lung described by Dr. Thomson of Birmingham. In one case where bacteriological tests were carried out the results were completely negative. The blood gave no agglutination to any of the organisms of the typhoid and dysentery group, including the *B. ærtrycke* and the *B. abortus*.

Finally comes an extremely detailed and valuable paper on the disease by Dr. A. P. Thomson and Dr. W. T. Hillier in the *Lancet* for February 22nd, 1930, which is quite the most complete account yet presented in the literature. This refers to no less than 21 cases, of which 19 were clearly cases of human psittacosis, and 2 were also probably due to that

disease. The authors give the following general clinical account of the disease:—

"It is fairly accurate to say of the severer cases that they resemble typhoid septicæmia in retaining a slow pulse, despite a high continuous fever. Even before the development of the unusual pulmonary signs, however, certain features distinguish them from true typhoid; the onset is usually more sudden and the temperature rises more rapidly. Headache is intense, generally occipital, and often associated with slight cervical rigidity. Epistaxis occurred in one patient. Sweating was sometimes severe. Diarrhoea and vomiting sometimes occur in the early stages, but as a whole the alimentary symptoms, apart from distension, have been trivial, except in the case of the three children. The spleen became palpable in one case, and then only for a few hours; no rose spots have been observed. In one case a typhoid-like relapse occurred. The outstanding feature of the clinical picture is the involvement of the lungs. At the onset signs of slight shifting bronchitis appear, to be followed in a few days by those of extensive consolidation manifested by impairment of the percussion note and the presence of tubular breath sounds. Still later the percussion note becomes completely flat, and breath sounds in the affected area disappear. The curious silence of the lungs may persist for some days after the temperature has fallen and the general condition has improved. A whole lung may be affected in this way. Resolution occurs very rapidly and completely, and is accompanied by fine crepitant rales. Repeated explorations of the chest have shown that these signs are in no way due to pleural effusion..... Certain negative features in the respiratory condition are important. Although cough is frequent and at times incessant, it is never painful, and expectoration is scanty and frequently absent; only twice was any rusty sputum obtained. Respiration is not hurried unless the area of lung involved is very extensive; it was easy and never 'pneumonic' in character. Pleuritic friction was found only once..... A diagnosis would be frankly impossible unless the history of contact with sick birds were elicited."

The authors then go on to discuss the bacteriological findings. In only one case did they isolate a bacillus corresponding to the *B. psittacosis*; on the other hand Professor C. J. Lewis reports that this organism was isolated from the cage of three of the birds responsible for this outbreak. Also positive agglutination results may be obtained. The authors therefore refuse to give a definite opinion as to whether the disease is due to a bacillus of the *Salmonella* group or to a filterable virus. Clinically, they claim, the disease is a separate entity with a very definite clinical picture of its own. Bacteriologically, its ætiology remains to be proved.

* * * * *

We trust that the above abstract gives a fairly detailed account of the present knowledge of psittacosis, as far as the literature to date has been studied. A further problem arises however. A mysterious epidemic malady of fowls, known by such various names as "Newcastle disease of fowls," "pseudo-fowl pest" of the Dutch East Indies, and "avian plague," due to a filterable virus, has long been known. Since about the middle of 1927 this disease has been very prevalent in India, and was first reported from Ranikhet in the United Provinces and Tanjore in the Madras Presidency in India about that date. This disease

(which has been found to be exceedingly prevalent among fowls purchased for experimental purposes at the Calcutta School of Tropical Medicine) has been widely epidemic in India during the last two and a half years, and has been the subject of special investigation by the workers at the Imperial Institute of Veterinary Research at Muktesar. The disease almost invariably proves fatal, and causes severe epidemics in fowl runs. The infected birds die in about 48 to 72 hours after showing the first symptoms of the disease; just before death they are almost completely paralysed and unable to stand, and a glairy mucoid secretion dribbles from their beaks. Ducks and pigeons are usually resistant, though they can be infected artificially. Mr. H. Cooper, M.R.C.V.S., of the Imperial Institute of Veterinary Research at Muktesar, has found that the serum of birds which have recovered from this disease has a most efficient protective action when inoculated into susceptible birds, and is at present engaged on an experimental enquiry into this "avian pest," as the disease is usually termed. (The disease is quite different from avian Pasteurella infection, and blood cultures remain sterile.) Crows are very susceptible, and possibly the unusual mortality noticed among crows in Bengal and the adjacent provinces in 1929 was due to this disease.

It will be noticed that Bedson, Western and Simpson have raised the question of the possible relationship of psittacosis of parrots and other birds to "avian pest"—both diseases being due to a filterable virus. The present world-wide outbreak of psittacosis is certainly the most important that has ever been recorded, and the investigations with regard to it are likely to contribute materially to our knowledge with regard to diseases due to filterable viruses. Whether cases of psittacosis have or have not occurred in India one does not know; it seems unlikely that the infection should have been imported direct from South America into India in the form of infected parrots. On the other hand, "avian pest" is at present extremely prevalent in India, and perhaps the workers in this country may be in a position to assist in the general world-wide enquiry. The present outbreak of psittacosis appears to be unique in history and to afford to medical research workers in several different countries unique opportunities of solving the problems concerned with this curious disease.

SPECIAL ARTICLES.

THE POSITION OF PSYCHOLOGY IN THE TEACHING OF MEDICINE.*

By OWEN A. R. BERKELEY-HILL, M.D. (Oxon),
 LIEUTENANT-COLONEL, I.M.S.,

Superintendent, Ranchi European Mental Hospital.

I do not think that any practitioner of medicine would maintain that the great developments in medical science during the last 100 years have brought about therapeutic successes commensurate with the increase in our medical and surgical resources. In other words, medicine continues to fail in its attempts to deal successfully with a problem which is its special concern. One of the consequences of this is that there exists among the public a considerable mass of ill-will against the medical profession, as well as a steady increase of fraud in every branch of therapeutics. Many doctors, probably the majority, will say that this has always been so, and, in all probability, always will be so. Although there may be good ground for adopting this attitude, no one could argue that the medical profession as a whole is entirely indifferent in these matters. Throughout the world there exist medical organisations to restrain the activities of unqualified practitioners, and to regulate the curricula of medical

*Based on a paper read before the Medical Section of the All-India Science Congress, January, 1930.

teaching. But in spite of these precautions, the quack flourishes and consulting rooms are full of people seeking for the relief they never find. Obviously there is something wrong somewhere and, I maintain, it is our duty to try and locate and identify the source and nature of the trouble. To the psychologist, perhaps inevitably, the idea will at once occur that part of the trouble at least may lie in the fact that medical practitioners have always shown a curious disinclination to attach any importance to the Hippocratic injunction always to pay strict regard to the mental as well as physical aspect of disease, when diagnosis and treatment are under consideration. One result of this neglect has been to lead medical practitioners more and more to treat a phantom man and to ignore the real man, that is, a living organism composed of a mind as well as a body. Further, the enormous accretion of knowledge through the development of scientific research has favoured this procedure so that we find nowadays the most elaborate specialisation in medical practice, with its inevitable tendency to regard a man as something made up of bits of things like what the anatomists show us in the dissecting room or what the histologists show us under the microscope. These so-called specialists seem quite satisfied to ignore the fact that each discernible part of a man is inextricably interwoven with every other part so that failure of function in one or more of the parts must involve repercussions throughout the whole organism. To the psychiatrist this attitude towards disease is incomprehensible because he knows something of the central nervous system, with its sympathetic and para-sympathetic systems. He knows (or he should know), something of the work of Cannon on bodily changes brought about by certain strong emotions. Last, but by no means least, he knows by his study of the ætiology of diseases like conversion hysteria, how a mental conflict can appear as a physical symptom. A good many years ago, when I was a medical student, I was greatly impressed by a remark of an old and deeply experienced general practitioner who said that it is not so important to know what sort of disease a patient has as to know what sort of patient has a disease. Although this view may strike some of our modern practitioners as thoroughly cynical, I would like to point out that it nevertheless contains an immensity of wisdom in that it embodies the quintessence of therapeutics, namely, that the concern of medical practice is not with diseases but with diseased people. To emphasise the great practical importance, apart from the scientific validity, of never failing to treat the diseased organism as a whole, mind as well as body, I will quote an example or two from my own experience. Some years ago, I had occasion to consult an eminent London physician about a peculiar type of furunculosis from which I was

then suffering. He prescribed ionisation. I begged him to suggest an alternative because, as I explained to him, even the mildest electric shock causes me considerable distress. He pool-pooled my protest on the ground that the electric current would be so mild I should hardly feel it. In the end I had to give way and the treatment began. My physician's own nurse arrived with the apparatus and one of my arms was placed in a basin containing a solution. I warned the nurse to keep the electric current very weak and she agreed to do so. All went fairly well for a few moments although I was in an agony of apprehension. Suddenly the nurse increased the current very slightly, but this slight increase was too much for me. I plunged as if I had been tetanised. The contents of the basin went all over the nurse and the battery got such a kick from me as to send it flying across the room. Now none of this need ever have happened had this eminent London practitioner been aware of the Hippocratic principle to treat patients and not diseases. Because he preferred, and that too in spite of a warning, to treat boils instead of a man with boils, he procured his nurse a warm saline bath and had his battery broken, not to mention making me worse than I was already for he put me in a thoroughly bad temper.

Let me take another instance. Some years ago I was asked to treat an elderly unmarried Englishwoman for a severe psychosis. In the course of the examination of her physical state, I was astonished at the number and size of the scars left by surgical operations on her abdomen. I found out in due course that my patient had been a very attractive girl and had been engaged to be married six times to five different men; twice to the same man. Each engagement had lasted only a short time when she broke it off and became seriously ill. On each occasion she was admitted into hospital and underwent a laparotomy. Two of the surgeons who operated on her were men of high reputation, while the others were of only average competence. Now not one of these surgeons seems to have suspected there was a mental factor in the case; they just "treated" the abdominal conditions. But had any one of these surgeons been taught to take the Hippocratic standpoint as his starting place for a diagnosis, he would almost certainly appreciate the true significance of the situation and referred his patient to a psychiatrist for a further opinion. I feel certain that had this girl been seen by a competent psychiatrist in the first instance, she would have escaped the development of the psychosis in which she eventually ended her life. I have little doubt in my own mind that these illnesses were the product of a strong feeling of guilt; in other words, they were self-inflicted punishments, for when I taxed her with this point of view she was extremely indignant

and rushed from my room, violently closing the door after her in such a manner as to pinch severely one of her fingers in the jamb. Hearing her cry out with pain, I followed after her and asked what had happened. She held out for my inspection the third finger of her left hand. "Why," I said, "you have gone and punished yourself again. You have pinched the finger on which you will never wear a wedding ring."

This case leads me to mention another type of trouble which is frequently puzzling to the ordinary practitioner. This is a peculiar variety of so-called "accident" which may result in any form of injury. The striking feature of these "accidents" is that the injured person, so far from being distressed at what has happened, seems quite resigned, indeed, sometimes almost pleased. Now anyone who undertakes to examine into the history of such accidents, will surely find that the patient either made no attempt to save himself, e.g., from falling, or had taken pains to get into a dangerous situation. Here again we are dealing not with accidents in the usual sense, but with self-inflicted punishments motivated by a strong sense of guilt. Of course, the proper treatment in such cases is to treat the feeling of guilt as well as the actual injury.

Now what is the remedy for all this muddle and waste? I believe that the remedy lies in a thorough overhaul of our existing methods of teaching medicine, with the cardinal purpose in view of re-establishing the importance of the mental side of the organism in the aetiology of disease as well as in therapy. That medical practitioners, with the exception of psychiatrists, are profoundly ignorant of psychology, ceases to be a matter for surprise as soon as we realise the place psychological medicine takes in our medical curricula. Psychological medicine, if it appears at all, does so as a more or less elaborate course in formal psychiatry, although one might have presumed that a moment's reflection would have been enough to show that the ability to differentiate types of dementia or to diagnose between manic-depressive insanity and general paralysis, is not the best equipment for any type of medical practitioner except a specialist in mental alienation.

To achieve therefore anything approaching a sound medical curriculum, we must scrap forthwith the whole of the existing programme in formal psychiatry and replace it by another which is not only basically scientific but of practical utility. To begin with, I would suggest a simple course of instruction in normal psychology. To follow this I would recommend two alternative courses, one for medical students who intend to make psychiatry their special study, and another for those who intend to take up general practice or to specialise in any branch of medicine or surgery, including dentistry. This latter course would comprise a

training in the aetiology of the neuroses as well as a study of the mental correlations of physical disease. Special emphasis would be placed upon the common psychic reactions associated with impaired function of the eyes, nose, teeth, heart, alimentary canal and genital organs. For example, the attention of students would be directed to the interesting observations of Inman on the mental aspect of defects in visual accommodation, photophobia and strabismus. A good number of oculists would be astounded to find how often the habit of wearing deeply tinted glasses is founded on an intense fear of darkness in childhood. Similarly the unconscious association of the nose with the penis as illustrated by endless vulgar sayings and jokes, will often lead to an anxiety about a possible venereal infection or a diminution in sexual potency, expressing itself in an anxiety about the condition of the nose. Not long ago, I was treating a female patient who had spent quite a small fortune in visits to rhinologists on account of a mild chronic rhinitis, when a careful examination into her case revealed that the anxiety about her nose really belonged to her clitoris. In like manner, anxieties about the condition of the mouth in women often disclose a transference upwards of an anxiety about the vagina. Here again, folklore and the sayings of common people show how closely are the mouth and vagina related in the mental sphere. It would be necessary to outline the symbolic significance of the extraction of the teeth as a punishment for masturbation for the better instruction of dental surgeons. The heart, that organ *par excellence* of mental repercussions, has almost a psychology of its own due to its deep and age-long association with the feelings of love and passion. Indeed, a very superficial acquaintance with the anxiety states is sufficient to show how intricate is the mental aspect of cardiac disease. Then the alimentary canal provides a rich field for psychic repercussions, especially as regards the acts of vomiting and defaecation. But perhaps the most important of all are the genital organs, especially those of the female. To psychiatrists the ignorance of the ordinary medical practitioner and even of many gynaecologists of the mental repercussions of disorders of the female pelvis and genital organs, is positively staggering. Many gynaecologists perform double ovariectomy, hysterectomy and salpingectomy without, it would appear, realising that a final and irrevocable prohibition to the consummation of the biological destiny of a woman is an affair not to be lightly undertaken. Then in respect to such conditions as vaginismus and dyspareunia, the most amazing remedies are applied without a thought that the condition may be entirely psychic in origin as, indeed, it nearly always is.

I will conclude with a few remarks on the psychological aspects of certain forms of

therapy. I have alluded already to the objection to employing electrical treatment to persons of certain psychic constitution. Massage is a form of treatment which may be highly offensive to chaste women who have erotic feelings when their skin is touched. Likewise, the use of syringes, hypodermic or otherwise, may be, and frequently is, very repugnant to some female patients and to certain types of homosexual men. The syringe and its action is for them too closely reminiscent of the male organ and its functions. Then it should never be forgotten that any kind of medicine in the form of a draught is frequently associated in the unconscious with semen. Hence the objection some women have to taking medicine by the mouth as well as the fondness of others for so doing and the habit some women make of keeping the prescriptions of their favourite doctors.

I have little doubt that much of what I have stated will meet with incredulity if not with derision. The only reply I can make to those who would either disbelieve or deride is: "Don't laugh at me. Just try for yourself and see what happens."

THE SCIENCE OF DISEASE.*

By S. R. CHRISTOPHERS, C.I.E., O.B.E., K.H.P.,
F.R.S., F.A.S.B.,

COLONEL, I.M.S.,

Director, Central Research Institute, Kasauli.

(Being the presidential address to the Seventeenth Indian Science Congress, Allahabad, January 1930.)

YOUR EXCELLENCY, LADIES AND GENTLEMEN,

Before coming to the subject proper of my discourse to-day I have the pleasant duty to perform of welcoming all of you here to the 17th Meeting of the Indian Science Congress. Unlike some Scientific Congresses that have been held in India the Indian Science Congress is in inception and scope one intended primarily for India's own scientific workers. It is therefore worthy of our fullest support and of our efforts to make it as great a success as possible. I need hardly point out the high position India has taken in many scientific subjects. In physics, chemistry, zoology, botany, geology, agricultural science, meteorology, medical research and other branches of Science Indian workers have added considerably to the sum total of the accomplishments of science, and I feel very deeply the honour of addressing this audience in which a number of those who have taken part in this work are present.

I found myself at first in some little difficulty to decide upon a subject that would be appropriate. It seemed most natural to speak on some medical research subject with which I was specially conversant. But this was perhaps too restricted a view to take for such a gathering as the present in which all sciences are represented and I sought for some general question that might interest you. Yet when I began to venture into realms that were not my own I felt a certain trepidation, since specialization now makes it very difficult for an ordinary person to speak without danger of tripping in any subject but his own. Eventually I decided not to roam too far, untrammelled by that strictly professional knowledge which many of you here possess in your own subject and, still

within the safe bounds of my own general territory, to give you a brief sketch of the nature of the field covered by medical research, or as I prefer to it here the science of disease. Coming as medical research does into close relationship with many sciences, each of you may possibly be interested in at least some part of my remarks. I was the more supported in my choice when I remembered that there is a general interest taken in matters of health and disease and that, perhaps if I failed to interest you as experts in your own particular science, I might still possibly approach you on a subject of general public importance and interest.

At the bottom of all questions of health, of curative or preventive medicine, or of medical art lies the necessity of knowledge of the causes of disease. The science of disease is therefore the very root of medical research. We cannot know what is required to maintain health until we know what may cause departure from this, and we cannot usually cure or prevent without knowing how diseases are caused. It is because just this knowledge, so simple when attained, so overlain in incredible secrecy until so attained, is so difficult and precious to come by, that medicine has had such an uphill fight. It has been both medicine's trial and honour that the subject it has had to deal with is not simple and straightforward but bound up with what, even in this present day, are among the most advanced developments of science. Its chemistry as we now realize is mainly colloidal chemistry since living matter consists of colloids, its biology lies in the subtlest regions of parasitology and the host's reaction to invasion, its physics deals with the electric charge of proteins and such like things.

Just as astronomy is the science of the stars, biology the science of living things, and seismology the science of earthquakes, and so on, there is clearly a science of disease, though curiously enough it seems to have no name. Nor is this science unimportant or merely altogether the application of other sciences. It has its own field, its own techniques and its own extensions into high matters, which cannot strictly be put under chemistry or biology any more than can astronomy be usefully considered as merely physics.

I propose then briefly to indicate the role of this science, including its practical importance to mankind, to give a very brief history of its growth and development, to describe some of the features of its modern progress that have especially so far seemed to lead to advance and, lastly, I shall go on to some lines of development in which medical research has advanced into fields which are peculiarly its own and in which, though its methods are, as they must be, those of the sciences physics, chemistry, biology and the like, it would appear to have trodden new or unexpected ground.

The Role of Medical Research.

The enormous practical utility in human life of a knowledge of the cause of disease is undoubted. It is often said of progress in an individual career "What serves it if a man gains the world and loses his own soul." A somewhat parallel case could be made regarding the enormous advances that have been made in human progress depending upon mechanical and other sciences. Without the means to control disease humanity lies helpless and open to attack. The conquering hero dies of cancer, the powerful emperor is sick of a fever. Disease is the most remorseless, the most cruel, the most continuous in its action of any of the great physical ills that threaten and control mankind. Of the three great terrors sword, famine and pestilence—pestilence, if we mean by this disease, has easily first place. War, at least now, in any given country is temporary, famine is episodic, but disease is ever present.

This may sound an exaggeration, but probably few but medical men fully realize the terribleness and cruelty of disease. Insanity, ulcers, pain, blindness, deformations, it is all misery. It is often the fashion

* Published by kind permission of the Council and General Secretary of the Asiatic Society of Bengal.

with those who do not see much of real disease, as for example that curious body the Christian Scientists, to speak of disease as though it were a merely something a little irregular, a lapse in mental health. But though this may be the view of the fortunately healthy it is not the picture seen by those whose business brings them into close contact with real disease. It would be a terrible thing if the boon of anaesthetics, the reliefs of surgical and medical treatment had never been developed as they are now. Further, to disregard the individual and think of disease as afflicting communities it is easy to picture what forces of disorder and death might at any time make their appearance, populations ravaged by plague and ignorant of its cause, civilizations destroyed by malaria and knowing not whence it came, men marching athwart the prevailing wind to escape cholera which they carried with them as used to be done. All such thoughts show what a *necessary* science is the one we are discussing. But for many, many centuries the necessity was seen, but this did not help knowledge.

The History of Medicine.

The history of our science, if in these early days one could call it a science at all, takes us back a long way. Reference to medical subjects occur in the Vedas at a date estimated to be as early as 1500 B.C. Sanger draws attention to an early Egyptian medical papyrus of about 1700 B.C. There are also Mesopotamian and Minoan origins. It is usual to commence the story of medicine with Hippocrates. Hippocrates was a Greek physician born in the island of Cos off the shore of Asia Minor. But the source from which knowledge of Hippocratic teaching is derived is the so-called Hippocratic Collection, about 100 books by different authors belonging to different schools and periods dating from about the 6th to the 4th centuries B.C.

The Hippocratic school taught that the body possesses four humours, the blood, phlegm, yellow bile and black bile, a right proportion of which constitutes health and an improper or irregular distribution disease. About the real causes of disease one is safe to say nothing was known. It should not surprise us that the Hippocratic school, or indeed any ancient system, did not penetrate into the real portals of the causation of disease. For 2,000 years afterwards no further progress in knowledge was made and indeed there was for a long time retrogression. So much so that when with the revival of learning in Europe the authentic text of the old Greek practitioners of the Hippocratic school was made available these ancient writings had a very great effect in revivifying the study and practice of medicine. The humoral theory of the Hippocratic school had as much to be said for it and as little to be said against it in the 16th century A.D. as in the time of Hippocrates.

A great name in the history of medicine was Galen (130—200 A.D.). Galen developed the idea of Pneuma (spirit) penetrating all parts of the body and mingling with the "humours" in different proportions. He held the theory of "temperaments." The normal condition or temperament of the body depended upon a proper mixture or proportion of the four elements—hot, cold, wet and dry. At this time it was believed that combinations of these elements produced the visible universe, i.e., hot and wet made air, hot and dry fire, dry and cold earth and so on. In drugs were to be recognized the same elemental qualities, hot, cold, moist and dry, etc., and so came indications for their use. Galen's explanations and system passed down through the ages as accepted facts. Throughout the middle ages beliefs about physiology and hence disease were always based on Galen. A thousand years later men hesitated before they contradicted even some detail of Galen's dicta. The views of this authority were not the truth but he had a logical mind and he unfortunately explained things so well that everyone was satisfied. One wonders how much we may sometimes be doing the same thing at the present time.

Arabian medicine, i.e., the medicine which arose in the chief seats of the Moslem power in the Mahomedan Empire was a return in a sense to the old Hippocratic medicine, for the writings of importance are chiefly based on translations of Greek books into Arabic carried out under the Abbasid Caliphs at Baghdad. The Caliphs were attached to ancient learning, they collected manuscripts and had these translated by the most competent scholars they could attract to their court. Actual advance made was chiefly in the form of pharmacy and therapeutic uses of drugs. Islamic medicine was the medicine of Europe in the middle ages and remained so till replaced by other systems based again on the old Hippocratic and Galenian systems.

Science which had its beginnings in the 17th century was some time before it effectively assisted medicine. Looking first for the somewhat simple types of explanation to which it had grown accustomed, it rather tended to create more fallacies of the old type than real progress. Even when anatomy and physiology, mechanics, chemistry and the like had progressed some distance they had little real help to offer the difficult, intricate and complicated issues which, had they known it, were necessary to be dealt with in the science of disease. Even in the 18th century strange "systems" prevailed. The Brunonian system explained the processes of life and disease as due to the property of "excitability" in virtue of which the "exciting powers" called forth the vital phenomena of "sense, motion, mental function and passion." All exciting powers are stimulant. So diseases were recognized as sthenic or asthenic, the latter requiring stimulant treatment, the former sedative. Another system which arose in this time was that of Hahnemann, generally known as homœopathy, a name one is still familiar with.

It is with relief that one turns from all the endless machinations of the introverted human mind in these early times to the beginning of real progress based on scientific method. It would take too long to follow step by step what now happened in decades where previously one has been dealing with centuries, if not millennia. I must merely indicate a few or some of the major advances made when science at last entered the field.

Up to this we should remember that until the end of the 18th century no one knew that there was such a material thing as oxygen. No one up to the middle of the 19th century knew really anything of the microbic origin of disease, though as often happens a sort of theoretical deduction had been put forward in advance of actual knowledge. A Veronese physician, Frascatoro, held a theory which must at least be considered correct so far as it went, viz., a rational theory of infection in which he hypothesized minute bodies with the power of self-multiplication.

In 1615 Harvey discovered the circulation of the blood. About 1650 a way was found of constructing and mounting simple lenses of high power. In 1661 Malpighi by the aid of such lenses discovered the capillaries. In 1761 Anenbrugger introduced the stethoscope and Laennec (1781—1826) developed the application of so-called physical signs in medicine. In 1796 Jenner showed the protection given by cow-pox against smallpox and opened up the subject of immunity. Schwann (1839) and others showed the cellular nature of animal tissues and laid the first foundation of histology, cytology and much else. Pasteur (1822—1895) laid the foundations of bacteriology and Lister (1861) of aseptic surgery. Anaesthesia came into surgery in 1846 with the use of ether by Morton and (1847) chloroform by Simpson. In 1876 Koch demonstrated the microbic causation of many diseases and began the study of disease causing organisms as things which could be seen, described and grown.

Taking 1518, the date of the death of Leonardo di Vinci, who was the first to question the views of Galen as the very beginning of the new order of

things, we have by 1880 or in about 250 years progressed from the stagnation of two millenia and the unchallenged supremacy of Hippocratic medicine of 300 B.C. practically into present-day conditions, where in theory and execution medicine has become one of the greatest, though still almost, if not quite, the most complicated and difficult of all sciences.

Features of Modern Progress.

So far the underlying note had almost always been "cure." Early medicine was concerned primarily and almost single-mindedly with cure. With many even at the present day the idea of cure as the role of medicine predominates. It is only relatively recently that the importance of prevention in the individual and in humanity in the mass has come forward.

Another feature of modern and especially of preventive medicine that is called to mind by the discussion of the predominance of the immediate utilitarian idea of cure is what is very aptly put by Singer in his short history of medicine as the recognition of the "fallacy of the frontal attack." Many would have us picture as the highest ideal that of the worker who sets out to obtain a cure for some terrible disease. This would no doubt be a very worthy and high motive, but it is doubtful if to the world at large it is likely to be as effective as the perhaps more selfish but in the end more productive following of science for its own sake. Medicine, still an art, advances only on a basis of science. Its votaries and certainly its scientific staff would be wise to bear in mind one of the peculiarities of science, viz., that from apparently the most seemingly and almost apparently trivial discoveries have come the greatest benefits. Koch would never have seen the tubercle bacillus, nor indeed any of us, if men from the love of science for its own sake had not engaged themselves in those, what must have seemed in those times trivial, studies that resulted in the creation of the modern microscope, without which it is I think legitimate to say that no science of disease could ever have originated. Hence in the modern development of medical research the field must be wide, curiosity, that trait in human character which is the most powerful opener of secrets and apparently the key to the dominion of man over Nature, must point the way. This again raises issues which I do not propose to enter into here, which are nevertheless very important in the question of medical research administration.

The time which I can expect you to give me is limited and I must pass somewhat more rapidly if I am to cover the ground intended.

As Colonel Mackie has said in his excellent resume of Medical Research in India,* in medicine men at first depended on the unaided senses and such clinical and epidemiological observations as could be made without any very special outside help. With the microscope and delicate chemical and other tests there evolved the pathologist, bacteriologist, protozoologist, biochemist, parasitologist, entomologist and so on. This specialization is becoming increasingly inevitable and its degree more pronounced owing to the vast field which even a single one of these sciences embraces.

The evolution of medical research has followed these lines in all parts of the world but nowhere so remarkably as in the tropics where disease like vegetation flourishes in some sort of relation to temperature. The greatest outstanding feature in tropical medicine is perhaps the enormous advance in parasitology and the transmission of parasitological disease. All this advance has been for the most part very recent, in what may almost be called the Recent or Holocene Period, of our subject, speaking geologically, which may be said to start from the electrifying discovery by Ross that that age long mystery, the method of entry into the human body of the parasite of malaria, was after all only a special case of heteroxeny, by a parasite belonging to the class Sporozoa.

So enormous has been the development in tropical medicine in the 30 years that have elapsed since that epoch-making discovery that it is quite impracticable for me to sketch even in outline what has been achieved in any detail. I shall do better to consider in broad outline what has been the general effect of this advance on our special science, the science of disease.

To those actually concerned with the prevention of disease nothing becomes clearer than that any effective action against a disease is almost absolutely dependent on the knowledge of the means of causation. A good example is plague. Formerly plague was viewed in the light of a directly infectious disease. Thus sanitary cordons and such like measures were those first enforced. When the idea of microbic infection had gained ground indiscriminate disinfection was added. How many thousands of gallons of disinfectant, often quite unsuitable to destroy insect life, must not have been thrown broadcast killing only harmless saprophytes while real infection lurked in the living rats and fleas in safe retreat. To a demon it must have appeared like some grim game of blindman's buff, men seeking to destroy by blind indiscriminate ineffective action what, if they could have seen, they could have picked out selectively for elimination. A human case of bubonic plague we now know is comparatively harmless, the real danger lies in the epizootic conditions that infect the area and hence evacuation rather than cordons and disinfectants to destroy fleas rather than microbes, usually a different kind of chemical altogether, are the proper things to use, and further and more fundamentally, we know there should not be such habitations as are suitable to infestation by rats or places where grain is kept that are not rat proof and so on. The same exactly has been the case with malaria. People believed they were inhaling miasma, all Nature as it were exhaling a poison, when in reality the source was concrete, a little fragile mosquito that individually could be crushed with ease and against which any individual with reasonable care can completely protect himself. We do not fear malaria now when we are in the primeval swamp, but when we come to our camp amongst other humans who have the disease.

Further it is not enough to know only the broad fact of how a disease is transmitted. We must know every detail in such transmission. We must know intimately the life histories of mosquitoes, fleas, lice and other insects, the resistance of organisms to desiccation, to chemical substances and so on. We must know not only that some disease is due to faulty diet, for not all diseases are transmitted, but we must know with exactness the chemical and other characters that are lacking.

We now know pretty effectively the causation and details of transmission of plague, malaria, filariasis, typhus, relapsing fever, beriberi, leprosy, enteric, hookworm anaemia, schistosomiasis and numerous other diseases.

Relation of Medical Research to other Sciences.

All this has not come about without a great deal of drawing upon sources outside medical research proper, if we think of this as purely medical work, nor has it all been done by medical men though these have done a major share. Many workers in medical research are chemists, many not only use biological methods but are to all intents and purposes biologists. Specialization may in present times be considered unfortunate, but it is only fair to say that in this way only can the worker in one line get what he wants when he has to rely upon the services of another. It is often the fashion to make disparaging remarks about the dry as dust systematist, the man who counts the very hairs on an insect's tail, yet scarcely a move can be made without his tremendous knowledge of details in his own sphere, more and more the technique and methods of entomology, helminthology, protozoology, bacteriology, colloidal and physical chemistry and other sciences are found necessary.

* Souvenir. The Indian Empire. 7th F.E.A.T.M. Congress, 1927.

Medical research, dealing as it does with departure from the normal conditions of the body, has obviously a relation to physiology. Largely through the effects seen in disease has come our knowledge of the functions of the ductless glands and the part played in the physiology of the body by the secretions of these glands or hormones. Again in nutrition it is largely studies directed against disease which have made us familiar with the effect of the vitamins and of radiation in the maintenance of the normal functions of nutrition.

With biology medical research is very closely associated. The fact, that many diseases are due to parasites, has led to very close study by medical research workers of groups of organisms that otherwise might not have received such minute attention. The science of bacteriology which deals with a whole range of organisms, which we now know to play a tremendous role in Nature, arose largely in the beginning from a study of the cause of disease and this science, in one sense a branch of biology, is still very largely dealt with by medical science. The same with the protozoa, especially the great parasitic groups Sporozoa and Flagellata. The life histories of some of these, puzzles that have taken endless work to unravel, would scarcely have been revealed to us had their activities not brought them into the field of medical research and so focused upon them a specially intense effort. Even with higher parasites, e.g., the worms, science would have been poorer without the results of the patient and difficult studies which have revealed to what degree of complexity parasitism may proceed. The development of filaria in the mosquito, of dracunculosis in the water-flea, of schistosoma in the snail are examples. In entomology certain groups, like the mosquitoes, have almost been a preserve in the hands of medical workers or those who work at them knowing the great medical interest taken in this group.

The modern investigation of drugs and especially the search for effective therapeutic compounds of mercury, arsenic and antimony has added considerably to the stimulation of chemists in these subjects. Even more has the close association of the processes of health and disease with colloidal chemistry brought medical research activities into the higher realms of chemical research. A vast literature on immunology, really a study of complicated protein reactions, comes strictly perhaps almost under physical chemistry, though the techniques and chief results have been carried out in connection with the study of disease.

Nor is physics immune from the encroachments of the nameless science we are discussing. Questions of the electric charge borne by colloidal particles, adsorption and surface tension phenomena, and much else has been increasingly familiar in medical research laboratories in recent years.

Some Special Developments.

But the contributions to science of medical research, though they must naturally in a sense fall within the limits of physics, chemistry or biology, are not always merely applications of these sciences or subordinate additions to their findings. With a mention of some recent examples of such a kind, space now demands that I should bring my remarks to a close.

First I will take the very interesting subject of bacteriophage and the biological issues raised by this. From about 1917 a series of communications by d'Herelle clearly set forth the discovery of an entirely new phenomenon, in which the essential feature was the apparent eating up, or more strictly the solution, of the bodies of various kinds of bacteria under the influence of an invisible "enemy." d'Herelle was working at the bacteriology of the contents of the alimentary canal of locusts, seeking in fact for a virulent organism capable of being used in the destruction of these insects. When making plates in the usual way for the isolation of organisms it frequently happened that clear spaces were evident in the opaque growth of the bacteria under investigation.

These spots it was eventually clear were the results of the activity of some invisible agency which dissolved the bodies of the bacteria. Under the microscope when the process was in action one could see a vacuole appear in the substance of a bacterium which increased in size, and if others were present coalesced with these, until suddenly the minute bacterial body underwent complete dissolution. Transferring material from a clear spot to an unaffected area on the plate caused the phenomenon to repeat itself.

Not only was the principle causing this solution of bacterial substance invisible, but it was found to be capable of passing readily through the pores of a Pasteur Chamberland filter, a fact that showed that it was far more minute than the organisms with which it was associated. Further this principle was capable of indefinite self-propagation. If to a tube of culture a little of this principle was added, the bacteria which cause the nutrient fluid medium to be turbid were dissolved with the result that the medium then became quite clear. If a tiny drop, or fraction of a drop, from such a cleared tube were added to a fresh culture this also was cleared and such a process could be repeated for as many transplantations as one wished, the enormous dilution involved after a time making it quite clear that the principle, whatever it was, was reproducing itself actively in every tube. Evidently the principle had one very important character which we are accustomed to think of as proper to life, viz., it was capable of indefinite self-propagation so long as there was "food" for it to work upon.

Though invisible it was possible to show that this principle was particulate and indeed it is now quite well known that it is of the nature of a protein colloidal particle. The phenomenon is called by d'Herelle bacteriophagy and the particulate cause "bacteriophage."

Now is this principle alive? Hitherto biologists have dealt with life as tantamount to properties exhibited by the "cell." Always it is protoplasm, usually with a nucleus, which is supposed to be alive. In the bacteriophage we have something clearly very near a living thing which is clearly not a cell, nor is it protoplasm. I am not here to-night to say whether the bacteriophage particle represents life or not, but you will agree with me that here medical research has brought into the workshop of science something that can be easily investigated and which must be of supreme interest to the biologist.

d'Herelle believes that natural cure in disease results when the bacteriophage in Nature overcomes the infecting organisms. All the immunological process medical research has dealt with in such vast but confusing thoroughness he admits only as accessory phenomena, mere necessities of colloidal phases. What the practical importance of bacteriophage may be none can yet say. Even if it should have no direct bearing on the prevention of disease, which is unlikely, it is a new line of investigation into most fundamental regions of colloidal chemistry and biology, and who can say at this early stage where it may lead?

But the bacteriophage does not stand alone. It has close relationships with the so-called filterable viruses. When the microbial origin of many diseases had been demonstrated it was natural to believe that all infectious diseases must be due to some form of organisms even if one had failed to demonstrate this. And a certain number of diseases have eventually fallen under the microbial category though they for a time resisted the search for a causative microbe. But many have resisted every attempt and some of these are amongst the most deadly of diseases known, e.g., smallpox, rabies or hydrophobia and yellow fever. In many such cases it is now recognized that infection will pass through the Pasteur Chamberland filter and so it is probable that the causative organism, if it is an organism, has not been seen because it is too small for visibility. Further, infection is not thought to be the result of an organism in the

accepted sense, i.e., minute cells as the bacteria and protozoa all are, but to be probably of the nature of protein colloidal particles and for this reason they are known as "viruses." Indeed the bacteriophage seems to be only a special form of an entirely new type of living thing, i.e., if we are prepared to define life as ordinarily understood, and certainly smallpox, for example, if it is not due to a living thing is remarkably similar in its natural history to other diseases that are.

Yet if these viruses are living things they are something almost if not quite as far below the bacteria in size as these are below living things visible to the naked eye. And on account of their size they are subject to influences which do not affect the relatively large bacteria or protozoa. Bacteriophage, for example, when first added to a bacterial culture disappears entirely from the fluid medium, to appear only later when the bacteria are breaking down. In other words it appears to be subject to adsorption, which not even the smallest bacterium is.

There still remain diseases as outstanding puzzles as ever any disease has been, I need mention only cancer, and medical research, nameless as a science though it is, may yet strike many things in its own proper sphere which are of great importance in the general advance of science.

Medical News.

THE NORMAN GAMBLE FUND AND RESEARCH PRIZE.

THE Council of the Royal Society of Medicine has accepted, as a trust, the sum of one thousand pounds (£1,000) presented by Mr. Norman Gamble for the purpose of founding "The Norman Gamble Fund and Research Prize."

The Norman Gamble Research Prize of value £50 shall be awarded for the best original work in Otology completed during the four years previous to the month of October in the year of the award. The competition for this prize shall be open to any British subject, whether lay or medical, who cares to compete, whether or not such persons be holders of or candidates for grants in aid of research.

Grants in aid of research work in Otology may be made to any British subject, lay or medical, who may be recommended by the Committee of Award to receive such grants, whether or not such person be a holder of or a candidate for the Norman Gamble Prize. Moreover, such grants may be given either to persons who apply for a grant in order to carry out a specific piece of work, or to selected workers chosen by the Committee of Award to carry out certain specified work of its selection.

Any person to whom a grant in aid of research is made from this Fund shall, within such time as may be allowed by the Committee of Award, render a typewritten or printed report in the English language on the work which has been carried out under the grant, and the Committee of Award shall have the right to publish such Reports.

The Committee shall not make any recommendation either for the award of the Norman Gamble Prize or for any grant in research if the papers or work under consideration are not of a sufficiently high standard.

The Committee of Award will consider applications for the Prize and for grants in aid of research work in October 1930.

Applications for the prize and for grants in aid must be received by the Secretary of the Royal Society of Medicine, 1, Wimpole Street, London, W.1, not later than 30th September, 1930, and must be in accordance with the regulations stated above.

THE SUMMER 1930 SHORT POST-GRADUATE COURSE IN NEUROLOGY AND PSYCHIATRY IN VIENNA.

THE fifth intensive course in the above subjects is announced to commence on 23rd June, 1930.

The course will last six weeks terminating on 31st July, and will be conducted in English. It will be held for a minimum number of eight and a maximum of fifteen men. The fee is \$150, about £30 15s., including the subscription to the American Medical Association in Vienna [Alserstrasse (9) Vienna (VIII)], under whose auspices the course has been organized.

Applications with a banker's draft for \$40, about £8 4s., should be directed to:

Docent Dr. E. Spiegel, Vienna, I. Falkenstrasse 3, Austria. They will be accepted in the order in which they are received. Deposits will be refunded if the number of applications is insufficient for the course to be held. A card is issued which permits holders to enter Austria without paying the Austrian visa.

The more important of the clinical lectures will be held during the first three weeks of the course in which also the major part of the psychiatric section will be taken.

Further particulars as to the course may be obtained from Docent Dr. E. Spiegel, at the address given above.

It is understood that modest hotel charges in Vienna are about twelve shillings a day and that pension rates are much less. The American Medical Association in Vienna will supply this information.

BOMBAY MEDICAL COUNCIL.

THE following summary of the proceedings of the meeting of the Bombay Medical Council held on the 10th February, 1930, is published in the Press for information:—

Major General W. H. C. Forster, I.M.S., the new President, was introduced to the Council by Sir Temulji Nariman.

The Council considered a suggestion of Mr. V. K. Chitnis, M.B., B.S., that the Diploma in Ophthalmology which the Bombay University now grants be recognized for registration as an additional qualification, and resolved to accept the suggestion.

The Council considered an application for registration from Mr. J. H. Godbole, a Sub-Assistant Surgeon, who was refused registration in 1921 in consequence of his having been convicted in 1915 under the Military Law by a Court-Martial of the offence of committing an assault on his superior officer at Brighton, and resolved to admit Mr. Godbole to registration.

The Council considered a letter dated the 17th August, 1929, from the President of the All-India Medical Licentiates' Association communicating for favourable consideration a resolution No. 15 passed by that body on the 21st March, 1929, to the effect that due representation be given to medical licentiates on the Provincial Medical Councils according to their number on the Medical Register, and resolved that it was not advisable to give more representation to the medical licentiates on the Council as at present constituted, on the strength of their number only.

The Council considered an application from Mr. Ratilal Shrivastav, M.B., B.S., of Rajkot, for the restoration of his name to the Medical Register whence it was removed in September 1928 under section 9 of the Bombay Medical Act, 1912, for infamous conduct in a professional respect, and resolved that the name of Mr. Shah should not be restored to the Register at present.

The following six members of the Council were elected by ballot as members of the Executive Committee:—Khan Bahadur Sir Nasarvanji Choksy, K.L., C.I.E., Dr. Y. G. Nadgir, Sir Temulji B. Nairman, K.L., Dr. Dinshah M. Gagrati, Dr. Rajabally V. Patel, and Lieut.-Colonel R. Row, O.B.E.

EIGHTH CONGRESS, F.E.A.T.M.

We have been asked to inform our readers that the Eighth Congress of the Far Eastern Association of Tropical Medicine will be held from the 7th to the 13th December, 1930, at Bangkok. The programme for the first week is given below. The membership fee is £3, for which members not only have the right of attending the Congress, but also receive the official *Transactions* (which, for the Seventh Congress in 1927 at Calcutta ran into three very large and profusely illustrated volumes). Following the Congress, the week 14th to 21st December will be devoted to tours in Siam.

Those desirous of attending the Congress should communicate with the Local Secretary for the Congress in their Province. The Local Secretary for Bengal is Lieut.-Colonel A. D. Stewart, I.M.S., Calcutta School of Tropical Medicine and Hygiene. It is essential that early notice should also be given of papers which it is proposed to read or present at the Congress. General enquiries should be addressed to:—

The Far Eastern Association of Tropical Medicine,
c/o Hoofdkantoor van den Dienst der Volksgezondheid,
10, Paranattan, Weltevreden, Java.

The following is the detailed programme for the Congress.

Sunday 7th to Saturday 13th December, 1930.

Ten a.m. to 4 p.m. The Information Bureau will be open for registration of members, distribution of badges and literature, and selection of excursions, visits, etc., from 14th December, 1930.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

(Division of Tropical Medicine and Hygiene.)
Examination Result. 87th Term. October, 1929—
February, 1930.

Passed with Distinction:

Davidson, W. C., Winner Sorley, J. T.
of "Duncan" Medal. Strahan, J. H.
Inckett, C. J. Stratman-Thomas, W. K.
MacLennan, N. M.

Passed:

Adam, F.	Kneedler, W. H.
Adgie, C. R.	Kocher, S. L.
Affleck, R. C.	Krishna, B.
Black, J. J.	Little, W. R.
Burgess, R. C.	Lowther, N. N.
Cust, A. D.	Mackay, A. F.
Czarkowska, J.	Malone, E. K.
Dowdeswell, R. M.	Mirza, W. A.
Egan, E.	Miterstein, Z.
Farmer, A. P.	Powell, G. M. C.
Fratel, A. M.	Scott, W.
Gharpure, P. V.	Swift, S. H.
Gilbert, F. W.	Thyne, W. H.
Gowenlock, D. E.	Tilsley, G. E.
Grey, A. B.	Trim, E. A.
Harris, D. B. L.	Vine, L. E.
Holm, C. C.	Washburn, B. E.
Hutchinson, W. J.	Wig, K. L.
Johnson, P. D.	Williams, C. T.
Kinneard, G.	Williams, F.

Date.	Forenoon.	Afternoon.	Evening.
Sunday, 7th December.	10 a.m. Meeting of the Council.		
Monday, 8th December	11 a.m. Opening of Congress by H. R. H. Prince Paribatra of Nagor Svarga—the Minister of Interior—in the Chulalongkorn University Hall.	4-6 p.m. Sight-seeing.	8 p.m. Dinner given by H. R. H. Prince Paribatra of Nagor Svarga to official delegates, 9-30 p.m. Reception followed by performance of Lakon (Siamese classical dancing). (Evening dress with decorations.)
Tuesday, 9th December.	10 a.m. to 1 p.m. Meeting of Scientific Sections (in the University lecture-rooms).	4-5 p.m. Visit to Health Centres. 5-6 p.m. Garden Party by H. H. the Minister for Foreign Affairs.	
Wednesday, 10th December	10 a.m. to 1 p.m. Meeting of Scientific Sections (in the University lecture-rooms).	4-6 p.m. Visit to Sowabha Institute and Chulalongkorn Hospital.	9 p.m. Reception by H. H. the Minister of Public Instruction. (Evening dress with decorations.)
Thursday, 11th December.	10 a.m. to 1 p.m. Meeting of Scientific Sections (in the University lecture-rooms).	4-6 p.m. Visit to Siriraj Hospital.	9 p.m. Royal Command performance of Symphony Concert.
Friday, 12th December.	10 a.m. to 1 p.m. Meeting of Scientific Sections (in the University lecture-rooms).	1 p.m. Luncheon by the Medical Association of Siam. 4-6 p.m. Sightseeing.	9 p.m. Royal Command performance of "Khon" (Classical mask dancing.)
Saturday, 13th December.	11 to 12 a.m. General Business Meeting of the Association. Closing of Congress in the Chulalongkorn University Hall.		8 p.m. Congress Dinner. (Evening dress with decorations.)

THE INDIAN SCIENCE CONGRESS, 1931.

THE Indian Science Congress, 1931, is to be held at Nagpur in the first week of January, 1931. The President of the Medical and Veterinary Research Section is Dr. U. N. Brahmachari, M.A., M.D., Ph.D., F.A.S.B.

In view of the fact that an excessive number of papers have been received in past years, which has made it impossible for all the papers to be read in the time available, and necessitated the curtailment of discussion on other papers, it has unfortunately been found necessary to exercise a strict selection. Authors are requested to take note of the following points:

(i) Papers on Medical and Veterinary Research *must* be received by the Sectional President, Dr. U. N. Brahmachari, C/o The Asiatic Society of Bengal, Calcutta, not later than the 15th October, 1930, which is the last date for accepting papers according to the rules.

(ii) Only original papers, that is to say, papers which have not already been read or published in the same or similar form, will be accepted. Not more than two papers will be accepted from any one contributor.

(iii) Papers will not be accepted from individuals who have not paid their subscription. The General Secretary has asked us to particularly bring this matter to the notice of our readers.

(iv) Papers must be sufficiently short to be read in 20 minutes. It takes 3 minutes to read a page of foolscap intelligibly, apart from diagrams, slides, etc. Papers should not, therefore, exceed 7 pages of typed foolscap.

(v) Papers must be accompanied by 3 typed copies of an abstract of the paper. This abstract must not exceed 200 words, and should not contain any formulae or diagrams. *Papers not accompanied by such abstracts will not be accepted.* It is not fair on members of the Congress not to have due notice from the programme of what the paper is about.

(vi) All diagrams, tables, pictures, etc., should be reduced to lantern slides, or enlarged to posters corresponding in type to 6/18 Snellen.

(vii) Authors should not contribute accounts of their papers to the local lay press. It is hoped that it will be possible to arrange for a daily precis of the proceedings in the Medical and Veterinary Section to be sent to the press officially by the President of the Section.

(viii) Workers in Bengal and neighbouring provinces are requested to send their papers *before the 21st September, 1930*, when the Puja Holidays begin this year. The attention of authors is drawn to the resolution of the Executive Committee that abstracts of papers submitted after the last date (15th October, 1930), *shall on no account be printed in the advance copy of abstracts.*

Will our readers kindly take this notification as the first official intimation with regard to the 1931 Congress? We trust, further, that the members of the medical veterinary professions in Nagpur will co-operate to make the 1931 Congress a successful one.

There are three classes of members of the Indian Science Congress; viz.:—

(i) Full members; annual subscription, Rs. 10.

(ii) Associate members; annual subscription, Rs. 5.

(iii) Student members (who must be certified by the principal of their college to be such). Rs. 2.

Only full members have the right to read papers. Associate and student members may submit papers through a full member. Subscriptions should be paid to the Honorary Treasurer, Indian Science Congress, c/o the Asiatic Society of Bengal, 1, Park Street, Calcutta. Forms of application for membership can be obtained from the General Secretary, the Asiatic Society of Bengal, No. 1, Park Street, Calcutta.

Current Topics.

Cancer in Hawaii.*

IN an interesting address delivered by Dr. Fredrick L. Hoffman, LL.D., before the Pan-Pacific Surgical Congress at Honolulu on August the 17th, 1929, a study is presented of the contrast between cancer in the native Hawaiians and the same disease as seen among the white population of the American Pacific coast. The author's summary is as follows:—

(1) As far as it is possible to judge, cancer in Hawaii during the last five years has shown no pronounced tendency towards an increase.

(2) The cancer death rate in Hawaii is measurably below the average for most other civilized countries or localities.

(3) Cancer death rates according to racial composition show pronounced differences of outstanding importance, the most suggestive of which is the excessive mortality from cancer among native Hawaiians, which is in marked contrast to the general rarity of the disease in primitive populations.

(4) The most important form of cancer in Hawaii, as elsewhere, is cancer of the stomach and liver. No other form of cancer seems to prevail to a degree demanding specialized attention.

(5) Cancer of the female genital organs and the breast appears not to be excessively common among any of the various racial elements, but this matter demands further investigation.

(6) The most suggestive aspect of the problem, considered with reference to specific organs and parts, is the non-occurrence of cancer of the breast among Japanese women, which is in strict conformity to the rarity of this form of the disease in Japan. It would therefore be extremely valuable to make this matter a subject of a special study, particularly on the part of practising Japanese physicians in the Islands, who would have the best facilities for the purpose.

(7) Cancer of the lungs, which is still relatively very rare, is shown to have occurred in Hawaii, but to a much lesser extent than on the mainland.

(8) Cancer of the buccal cavity is relatively uncommon in the Hawaiian Islands, except cancer of the tongue, from which there have been ten deaths among the population during the five years under review.

(9) Cancer of the œsophagus is fairly common among the male population, there having been 27 deaths out of a total of 602. Cancer of the male genital organs is relatively rare. Cancer of the pancreas is relatively common, there having been 19 deaths, and 13 deaths from cancer of the prostate, out of total of 602.

(10) As shown by the table at the outset, cancer is not at present on the increase in the Hawaiian Islands, there having been 127 male deaths during the first of the five-year period against 128 deaths during the last.

(11) Among the women in the Hawaiian Islands the outstanding form of cancer is of the uterus, there having been 128 deaths from this form of the disease out of a total of 364. The disease is not, however, rapidly increasing, there having been 27 deaths during the first year of the period against 22 deaths during the last year and 33 during the mid-year 1925-1926.

(12) Cancer of the breast caused only 22 deaths out of a total of 364 deaths, or 0.06 per cent. There were two deaths from cancer of the breast during the first year, seven during the second, four during the third, four during the fourth, and five during the fifth. There is therefore no definite trend towards an increase. Most other forms of cancer among women are very rare.

* Published by the Prudential Insurance Co. of America, Newark, New Jersey, U. S. A.

(13) The cancer problem as regards the female population in Hawaii chiefly concerns the stomach and liver and the gastro-intestinal tract, as well as the uterus.

(14) Cancer deaths with a previous operation constitute about one-fourth of the total, which is less than one-half the proportion common on the mainland. This would be suggestive of much needless neglect or delay to which attention may be directed.

(15) The number of deaths coming to autopsy was only 137 out of a total of 966. It would be highly desirable if this proportion were much larger, to make sure of the terminal diagnosis.

(16) The number of deaths in hospitals is about 40 per cent. of the total, which is also about two-thirds of the proportion normal to the mainland. It is therefore indicated that there is need of more general hospital provision for the natives of the different islands, but I am not sufficiently familiar with the medical and hospital facilities to enable me to judge of the facts of the present situation.

(17) The average age at death from cancer in Hawaii is several years lower than for the mainland. For males the average age is shown to have been 57.7 years and for females 53.8 years. These averages, of course, are affected by the peculiar age constitution of the Hawaiian population, including as it does a large proportion of comparatively recent immigrants, mostly from Asiatic countries.

(18) As far as it is possible to judge, the registration of vital statistics in Hawaii is practically complete.

Treatment of Varicose Veins and Varicose Ulcers by Injection.

By REGINALD T. PAYNE, M.A. (Lond.).

(Abstracted from *The Lancet*, 17th August, 1929, Vol. CCXVII, p. 313.)

Technique of Injections.

THE quinine and urethane preparation is of the following formula:—

Quinine hydrochloride	..	4.0 g.
Urethane	..	2.0 g.
Aq. dist.	..	ad 30 c.cia.

The active principle causing damage to the endothelial lining of the vein is the quinine, the urethane merely raising its solubility in aqueous solution. On standing, the solution slowly deposits crystals of quinine hydrochloride; these can easily be redissolved by warming to body temperature.

The actual technique is similar for the two solutions. The patient stands in a good light and an Esmarch tourniquet or Martin's bandage is applied proximal to the proposed site of injection. The object of this is to render the veins prominent during the insertion of the needle, and in all cases it should be removed before the injection is made. The patient then lies down and the region of the proposed injection is carefully cleaned with ether. A 5-c.cm. Record syringe carrying a No. 17 needle is filled with the required amount of solution and introduced obliquely through healthy skin into the lumen of the vein. The plunger is then slightly withdrawn to confirm the fact that the needle is in the lumen. At this point the tourniquet is removed, allowing the vein to collapse and ensuring that the quinine and urethane solution reaches the vein walls in a high concentration. As a rule, 1 c.cm. in 15 seconds is about the average rate of injection, but no force must be used and the time must depend to some extent on the resistance encountered. Pressure is then applied with an ether swab over the site of injection and the needle is withdrawn, the swab being kept in position for two minutes. The puncture is dressed with collodion on a pledget of wool, and when dry the whole is covered with a small square of wool and firmly bandaged. The maintenance of digital pressure after injection, the collodion dressing, and the bandaging are designed to lessen the risk of leakage of blood mixed with injection

material into the subcutaneous tissues around the site of puncture. Leakage is almost certain to cause local complications. The patient goes home, and returns at the end of a week for further treatment. All the patient's usual activities are permitted, rest is not enjoined, but the normal reactions which follow injection are explained.

Considerable discussion has centred round the question of the position during the injection, many workers preferring to have the patient standing. This was done in some of the earlier cases but abandoned because many of the patients objected. On theoretical grounds, it might seem desirable to insist on rest for 10 to 15 minutes after the injection to prevent any possible aspiration of blood into the deeper veins, but this has not been carried out and no untoward effect has been noted.

Dosage.

It is advisable to commence with a small dose of quinine urethane solution and for the first injection 0.5 c.cm. is invariably employed. This has a twofold object, the first being to test the local reaction of the veins to the solution, and the second to discover whether or not the patient possesses any special idiosyncrasy towards quinine. Subsequent injections are, in practically all cases, 2 c.cm. per dose, which can generally be relied on to thrombose 5 to 6 inches of a vein. Larger doses may be necessary in a few cases, but more than 4 c.cm. should never be given at one sitting. It is important to follow cases closely to see exactly what degree of thrombosis injections are producing, for individual differences play a large part and injections must be regulated accordingly.

The technical details for sodium salicylate solutions are the same as for quinine, except in dosage. Three strengths, 20 per cent., 30 per cent., and 40 per cent. are used. Injections should begin with 2 c.cm. of 20 per cent. solutions, which will usually thrombose about 4 inches of vein. Later injections must be regulated according to the amount of thrombosis produced. If the 20 per cent. solution is adequate, injections may be confined to this; if inadequate the 30 per cent. or 40 per cent. solutions must be tried in doses up to 4 c.cm. until the requisite effect is obtained. It is important to bear in mind the fact that veins appear to establish a remarkable tolerance towards salicylate solutions, as a consequence of which they fail to thrombose. For this reason the surgeon should work as rapidly as possible up to a dose and strength which produces the required effect.

Whichever solution is used, I do not think it is desirable to attempt to produce more than about 5 inches of thrombosis each time; if more is done the method is likely to cease to be strictly ambulatory, owing to the discomfort produced.

Site.

In general, treatment should be commenced in the most distal part of the limb, and each succeeding injection given proximal to its predecessor. This enables the operator to distinguish at once thrombosed from non-thrombosed veins. An exception to this rule is made when the varicose condition involves the region of the ankle-joint. Veins in this position should always be left till all others have been treated; they are then usually found to be entirely symptomless and very much smaller in size. If, however, it is decided to inject this region, it is as well to bear in mind that boots and shoes are likely to cause considerable discomfort during the thrombosis.

Using the doses described above, injections will be necessary at intervals of approximately 4 to 5 inches along the course of varicose veins, and in this way the whole saphenous tract may be treated to within about 4 inches of the saphenous opening.

In the earlier cases, while the total amounts injected were the same as those now used, the dose was given at two or three sites spread over about 5 inches of vein. This has now been given up entirely in favour of the injection of the whole dose at one

site. The results have been just as satisfactory and much less discomfort is caused.

Reactions.

1. *Quinine.*—Injections should be entirely painless, apart from the prick of the needle as it penetrates the skin; pain during the injection shows that the fluid is finding its way into the subcutaneous tissues and is an indication for discontinuing the injection at once. Thrombosis begins between 12 and 24 hours after the injection and is accompanied by slight swelling, aching, and tenderness of the vein. This pain is invariably accentuated by postural changes, and is especially noticeable in the morning. As a rule the thrombosed segment becomes partially adherent to the overlying skin as a result of mild periphlebitis but, although this occasionally shows a linear bruising, redness is unusual. After about four days the vein begins to shrink, and this process continues for at least three months. Local tenderness disappears at the end of a fortnight, but bruising may take six weeks to clear up, and at times a slight permanent pigmentation is left. All these reactions are more severe where the vein is situated over bony prominences which prevent its sinking back into the subcutaneous fat. Patients show marked individual variations in the degree of reaction. The subsequent discomfort is in most cases slight and rarely limits activity. In the present series four cases lost two days' work each, and one case one day, in consequence of more than usual discomfort.

Constitutional effects due to quinine were observed in 4 per cent. of the cases and included nausea and vomiting, tinnitus, headache, and a transient intermenstrual loss. In women quinine injections must not be given during menstruation. No general quinine reactions were seen in the male cases.

Abnormal local reactions, due to leakage of blood mixed with the quinine solution into the subcutaneous tissues, are also occasionally seen. In their mildest form these consist of blood blisters, half an inch in diameter, which dry up in about three weeks. If the local process is more severe necrosis occurs, leaving a small eschar which heals in four to six weeks. These eschars were produced in eight cases in the first 500 injections, and in three cases in the last 1,000 injections. The high incidence in the former group was due to the fact that in these the punctures were dressed with collodion only, whereas in the latter group the special precautions described were adopted. It is highly important, I think, that this type of complication should be guarded against by all possible means, for it provides an entry for sepsis with all its attendant dangers. In the present series, however, no septic complication has been seen. This necrosis sometimes occurs at sites remote from the injection, through a vein which is very thin-walled at that point. In such cases the dosage has been too high. Three cases showed rather more extensive thrombosis than was intended, in that this reached from the region of the knee to the mid-thigh, a distance of 8 inches. These all occurred in veins which possessed no obvious tributaries and in which, therefore, the effects of stagnation were likely to be marked.

2. *Salicylate.*—The use of sodium salicylate solutions has in the present series been confined to cases which showed an idiosyncrasy towards quinine or in those associated with pregnancy. Salicylate invariably gives rise to considerable cramp-like pain during the actual injection, but the subsequent discomfort is usually less than with the quinine method. No local lesions have been observed, but the two solutions seem equally likely to produce these. Varicose veins rapidly develop a tolerance to sodium salicylate, and for this reason the doses and strength of the drug has to be increased as treatment proceeds. Occasionally this results in failure to achieve thrombosis even with large doses of the 40 per cent. solution. Quinine injections have never failed.

Results in Uncomplicated Cases.

I will not attempt to present the results in statistical fashion, as this is extremely difficult. Only too often varicose veins are but a part of the clinical picture, which is obscured in no small degree by other associated conditions, of which the commonest are flat feet, hallux valgus, and the various forms of arthritis. On the whole, therefore, clinical impressions appear to be more reliable. Since injection treatment gives 100 per cent. cure in cases not associated with other pathological conditions, it can, I think, be justly inferred that, in so far as the veins are concerned, similar results are obtained in cases where the picture is complicated by the presence of other diseases.

Even from a comparatively early stage of treatment patients begin to experience relief. Bandages and elastic stockings are abandoned, usually before injections are completed, although the final functional and cosmetic results are not seen until at least three months after all treatment has ceased. From the functional standpoint, patients in whom moderate activity was only possible with limbs swathed in mummy fashion can now work and play in comfort. From the cosmetic standpoint, limbs which once resembled Saxon gouty ballusters are restored to more conventional outlines. From both these standpoints, treatment appears to be equally successful in all the various types of veins. The small and early varix of the calf, the dilated and tortuous entire saphenous vein, and the advanced, diffuse, arborescent veins of the lower leg, all respond well. Injection methods are also applicable to the spidery varicules so often seen in women; these are often almost symptomless and in the present series they have only been treated when complicated by recurrent subcutaneous ruptures. Whichever type of case is considered, one of the most striking features of treatment is the remarkable recovery of tone and elasticity of the thinned and atrophic skin after obliteration of the veins.

All cases should be kept under observation for at least a year after treatment has finished. In the present series no case has shown re-canalization of a thrombosed vein when the varicosity was confined to a single main vessel where this could easily be recognized. In the type of case where the entire calf is an entangled mass of interlacing veins, prolonged observation is, however, especially necessary, for reactionary changes in the thrombosed veins often hide smaller veins which are still patent. Injection treatment offers no guarantee against the development of varicosities in other veins, but it does provide a simple means of dealing with these at an early stage should they arise.

Results in Ulcer Cases.

If trauma or infection should be superimposed upon an inefficient skin circulation, a particularly chronic type of ulceration is bound to ensue. In general, persistence of ulceration on the surface of the body is due either to chronic infection or to circulatory conditions so inadequate that repair processes cannot be carried on. The results of injection treatment show that the vascular instability is undoubtedly often responsible for the chronicity of the lesions, and that infection plays a secondary rôle. Varicose ulceration has in the past been cured by rest in bed, by the various forms of Unna's bandaging, and by surgical treatment of the veins; it is now curable by injection methods. The common factor underlying all these measures is the relief of venous congestion, temporarily, by rest and bandaging and permanently by operation or injection.

Before commencing injections it is best, in cases where the skin around the ulcer is in a very unhealthy state, to carry out this treatment for two or three weeks. Injections should never be made through the unhealthy skin which so often surrounds the ulcers. Coming into contact with the ulcer above will be found, in almost all cases, a large radicle of the internal saphenous vein. This vessel has been referred to

adequately, in relation to the organs and tissues innervated through it and in relation to the cerebro-spinal nervous system, to point out its developmental and general physiological relationships to the cerebro-spinal nervous system, and to set forth the more important pathological and clinical data bearing on the functional relationships of this division of the nervous system in disease."

The subject-matter is dealt with in a lucid and scholarly manner in twenty well-arranged chapters. Copious illustrations add to the great utility of the book. An exhaustive bibliography is appended at the end of the volume. We have great pleasure in welcoming this up-to-date treatise and commending it to those interested directly or otherwise in the nervous system.

S. S. R.

RECENT ADVANCES IN PREVENTIVE MEDICINE.—

By J. F. C. Haslam, M.C., M.D. (Edn.), M.R.C.P. (Edn.), D.P.H. with a chapter on the Vitamines. By S. J. Cowel, M.A., M.B., M.R.C.P. London: J. & A. Churchill, 1930. Pp. VIII plus 328 with 30 illustrations. Price, 12s. 6d. net.

It is interesting to note the change that has come over the meaning of the words "preventive medicine." The old narrow conception which limited the outlook of sanitarians to drains and damp proof courses has been replaced by a wider and truer outlook which really embraces not only its particular branches but also the whole of so-called curative medicine, certain aspects of sociology, economics and political legislation. It would be a large task to deal with every aspect of preventive medicine in these wide ranges that has made advances within recent years and Dr. Haslam has had perforce to limit the subjects dealt with, and he has confined his attention to particular lines of advances which illustrate the newer type of preventive medicine as contrasted with the older limitations of purely environmental sanitation. Every writer in preventive medicine will be grateful to Dr. Haslam for his excellent summaries, and we only wish he had been given opportunities to deal with certain other matters which have had to be omitted for want of space. Advances in preventive methods in tropical diseases such as malaria, hookworm, kala-azar and cholera have had to be omitted. We would have welcomed a separate chapter on the modern studies of epidemiology, especially the work of Topley, Webster, Dudley, Gill and others, though these are used to illustrate points in various chapters.

The subjects deal with are:—

Eugenics, Maternal Mortality, Wastage of young life, Childhood, Milk, Vitamins, Atmospheric conditions, Hygiene in Industry, and Active Immunisation.

In the first, the outlines of a modern practical eugenic policy are given and the possibilities and the results already achieved discussed. Some States have applied some of them legally mainly in the segregation of criminals, the sterilization of the unfit and feeble-minded and the production of "fit" certificates before marriage. Public opinion is not yet sufficiently formed to accept logical results, but in California where sterilization of 6,255 individuals has been carried out up to 1st January, 1929, the result has been recorded and opinion seems to be now that

(1) As a penal measure sterilization is not justifiable.

(2) It is not the function of the State to apply it therapeutically.

(3) Compulsory eugenic sterilization is reasonably workable under proper safeguards (especially on people who have become a charge on the State).

In the chapters on maternal mortality and the wastage of young life, especially the first month of life, the interdependence of these two mortalities is emphasised. Neither mortality has shared in the general fall in the death rates and close investigations have been made as to the reasons. It is a curious fact that countries in which there have been the greatest declines in infantile mortality in the first year of life still show high maternal and

neonatal mortalities. The studies of Kinloch and others are the best recent investigation of the facts. Toxic conditions including puerperal sepsis would seem to be the most potent cause of maternal death. The *Streptococcus hemolyticus* is the offending agent in the majority of cases and Kinloch's report points out how puerperal sepsis exhibits the phenomena of an ordinary droplet infection epidemic, and that throat carriers of the streptococcus spread the condition by spray infection of sterilized hands and instruments. Trauma also plays a part in increasing liability to infection, but in Kinloch's view does not fill the part to the extent which some obstetricians including Young, would assign to it. For remedy and prevention an ideal maternity service has been advocated, comprising antenatal clinics, an expert midwives service for normal cases (for sepsis is commoner in doctors' practice than in midwives), a specialist service (not just the general practitioner), maternity hospitals for abnormal cases, isolation hospitals for pyrexias and maternity homes for normal cases.

The wastage of life in the first month are due mostly to complications of labour; syphilis accounts for only 10 per cent. of neonatal deaths; investigation would go to show that the health of the mother during pregnancy and especially in the first month after labour is the determining factor for good or ill. Fetal injuries both in forceps cases and in uncomplicated cases (especially perineal tears) are a feature of statistical enquiry, and lobar pneumonia in the first few days of life is an unexpectedly large cause. The cause is obscure and it is often a colon bacillus infection.

The care of the pre-school child has received a great deal of attention. Striking photographs are given of school classes in 1894 and 1924, the differences in the facies, the expression, and the dress are extraordinary. One can pick out 10 month breasters in the 1894 class for every 1 in the 1924. Nursery schools have done a great deal to improve conditions and to remedy and prevent conditions which are all too frequently found when the first inspection by the school medical service is carried out. The question of adequate and suitable nutrition of the school child has received much attention. The defects are qualitative rather than quantitative, and supplementary meals of milk and cod-liver oil are now a common feature of school life. This is taken advantage of by large number of non-necessitous families on payment. The cause of dental caries has advanced in knowledge by the work of M. Mellanby on vitamin D. Whether defective structure or carbohydrate fermentation is the main factor in dental caries is still under consideration but M. Mellanby's work seems to have gained many adherents.

In the chapter on milk, there is a note on the average amount of milk consumed in various countries: 1 pint per head per diem is considered a desirable minimum, but most countries fall far short of this. Switzerland heads the list with 1.83 pints; Italy only 0.07 and the United Kingdom varies from 0.1 to 0.31. For chemical analysts, there is a useful review of several papers by Tocher. Chemical standards of purity must always be approximate and have a "herd" value. Individual cow's milk varies widely. Water is the least variable and fat and protein the most variable. Tocher points out that as the water content of the original milk is never known, so the percentage of added water can never really be stated with accuracy, being determined on the hypothetical value of solids-not-fat. All public analysts in India should read the original papers of Tocher.

Irradiated milk has been used to treat rickets and benefits certain anaemias in children to a very large extent. Certain epidemics of sore throat have been shown to be milk-borne; the cause is a hemolytic streptococcus which has infected the udder through an infected human being. The same mechanism would appear to be true in scarlet fever. An interesting epidemic of arthritis due to milk is noticed. A useful

discussion of the problem of improving the milk-supply is given and the pros and cons of the two views discussed, e.g., whether to aim at milk free *ab initio* from pathogenic germs and of high nutritive value or at one which despite sundry defects will be safe; the first is expensive and difficult though ideal, the second is probably dangerous but has practicability at present. The present system of "grading" is defective in that there is no standard of bacteriological purity for ordinary milk, while the grading is misunderstood by the public. Grade A (third in order) is by its name taken to be the highest grade. The American views on pasteurisation seem sound, i.e., when a milk supply cannot be adequately inspected and controlled by the sanitary authority (as in rural areas), it is better to insist legally on pasteurisation. The interesting experiments on the great advantage of giving children milk carried out by Corrie Mann and in Scotland are described; the growth qualities are not dependent on the cream, for skimmed milk is equally efficacious. A good comparative description is given of the attempts to eradicate bovine tuberculosis and to lessen its dangers—the Bang, Ostersteg, the English and the American systems being contrasted. The B. C. G. system of immunizing children by living attenuated tubercle bacilli is considered as non-proven; with a leaning towards dubiety.

An interesting history of the vitamins is given—this work has received wide publicity, however, and most will be already familiar with it.

One of the most informative reviews is that on atmospheric conditions. Modern textbooks are still weak and indefinite on the kata thermometer and the effective temperature. The uses of the kata thermometer, its calibration and its limitations are very well described and nomograms for comparing kata readings, ordinary readings, and air velocity with relation to conditions of comfort are figured. A comparison of the American effective temperature methods of estimating comfort conditions with the kata method is given, with a balance of favourable opinion, inclining to the latter. The important conclusion of Vernon is worth while recording here that to reduce an over-heated body of a man engaged in hot and heavy work, the temperature should be first reduced, then the clothing, whilst increase of air velocity has little effect. There is a great field of work open for this sort of study in India—the observations on the Cotton Industry Commission and of Col. Jolly in Burma are the only systematic records available.

The last chapter deals with active immunization and the work leading up to the Schick's and Dick's reactions are succinctly given. This work and the active immunization by toxin and toxoid-antitoxin are known to those interested in prevention. The point is noted by Dudley, however, that a secondary exposure to infection (natural or artificial) produces a greater and more rapid immunization than is accounted for by the dose alone. A primary sub-clinical infection or stimulus, followed later by a dose of T. A. T. will give a rapid and large immunization. This explains some of the phenomena exhibited by immunization by T. A. T. The claims of benefits of wholesale immunization by T. A. T. made by certain observers, especially American, are very critically examined and mostly found wanting. The claims of special measures made during the natural decline of an epidemic period will seldom stand the test of time. In New York for instance, Forbes in 1926 wrote that "coincident with active immunization against diphtheria, the death rate fell from 12.7 per 100,000 in 1918 to 7.9 in 1926." But in 1927 the death rate was 12.7 per 100,000 and 10.7 in 1928. Other instances are cited. Dr. Haslam points out that it is futile to quote death rates for an odd year or two without reference to the existing trend as evidence of the success of immunization. There is probably no more common mistake made by enthusiasts for new methods. Dr. Haslam's English mind is suspicious of "slogans" which are so popular in America, but recognizes that so far as concerns the expediency of methods of propaganda in any place, those on the spot are the only judges.

It will be seen that the contents of the book appeal to every physician, and more especially to those actively interested in preventive medicine. The omission of certain subjects noted at the beginning of this note is regretted only because Dr. Haslam could have dealt with these also so efficiently.

A. D. S.

THE AFTER-TREATMENT OF OPERATIONS: A MANUAL FOR PRACTITIONERS AND HOUSE SURGEONS.—By P. Lockhart-Mummery, F.R.C.S. (Eng.), M.A., M.B., B.C. (Cantab), 5th Edition. London: Baillière, Tindall and Cox. Pp. IX plus 281 with 37 figures in the text. Price, 7s. 6d. net.

IN the preface to this, the fifth edition, the author draws attention to the great change which has come over the after-treatment of operations during the last twenty-five years, and claims some of the credit for this advance. The first edition was published in 1903. In the present edition the chapters on shock, post-operative thrombosis and embolism, have been largely rewritten. A chapter has been added on blood transfusion and on post-operative urinary infection. The chapters on abdominal operations have also been considerably altered.

The first chapter is introductory and deals with such post-operative questions as posture, beds, sleeplessness, pain, acidosis, thirst, flatulence, etc. Chapter II describes the treatment of the wound; the next seven chapters deal with such important matters as hæmorrhage, blood transfusion, surgical shock, infection of the urinary tract, post-anæsthetic complications, thrombosis and embolism, and rashes and drug-poisoning. The remaining ten chapters of the book are concerned with the after-treatment of operations performed on various parts of the body. Chapter V on surgical shock is particularly valuable, especially to young surgeons, and ends with the important observation that the "best results will always be obtained by preventing shock rather than by treating it." An appendix on "diets" completes the book.

It is not necessary to describe at greater length so well known a book. It is of convenient size, cheap, and contains nothing but practical instruction, invaluable to all those who have not had the opportunity of learning by personal experience—sometimes a lengthy and bitter process, particularly for the patient!

F. P. C.

A MANUAL OF MIDWIFERY FOR STUDENTS AND PRACTITIONERS.—By Henry Jellett, B.A., M.D. (Dub. Univ.), F.R.C.P.I., L.M. and D.G. Madill, B.A., M.B., B.Ch. (Dub. Univ.), L.M. Fourth Edition. London: Baillière, Tindall and Cox. 1929. Pp. XII plus 1280 with 570 figures in the text. Price, 25s. net.

JELLETT AND MADILL'S is one of the standard books on midwifery in the English language. The last edition appeared nearly 8 years ago so that this new edition is welcome. We gather that the revision has mostly been carried out by the second author as the former has now retired from active practice.

This edition appears to be somewhat larger than the previous one. The book has been revised throughout and the chapters on eclampsia, the treatment of contracted pelvis, and the ætiology of antepartum hæmorrhage have been rewritten, and new sections on anæsthesia during labour, pyelitis during pregnancy, nephritic toxæmia and pre-eclamptic toxæmia have been added.

This edition has maintained the high reputation of its predecessors and at the same time has been brought thoroughly up to date. We can strongly recommend it to both student and practitioner.

The format of the book is very satisfactory; the paper, though opaque, is thin enough to allow the twelve hundred odd pages to be bound in a volume of reasonable size. The printing is clear and the illustrations are well reproduced.

Annual Report.

ANNUAL REPORT OF THE EXECUTIVE HEALTH OFFICER, BOMBAY, FOR THE YEAR, 1928. BOMBAY, TIMES OF INDIA PRESS, 1929.

This report by Dr. J. E. Sandilands, M.D., D.P.H., contains much interesting matter.

The area of Bombay city is 23.54 square miles, and its estimated population in the middle of the year 1928 was 1,298,708. The birth rate was 18.5, per mille, if calculated on the estimated population, or 20.4, if calculated on the figures of the 1921 census. As is well known, birth rates in the great Indian cities are not a true measure of the fertility of the population, owing to the prevalence of the custom of married women going back to their homes in the *mofussil* for their confinement. The birth rate in 1928 was the highest recorded since the introduction of records of births in 1866. As usual, the number of births in the second half of the year was considerably higher than in the first half of the year. Especially high birth rates were recorded among Anglo-Indians (46), and Jews (31); the lowest birth rate was that for Europeans (9.7).

Deaths numbered 27,312 as against 27,633 in 1927; a ratio of 21.0 per mille, and the lowest figure so far on record for the city. Males greatly outnumber females in the city, and accordingly show a much greater total number of deaths; actually the death rate is higher among the female population. In Diagram B a comparison is shown between the death rates from the different diseases for (a) the years 1923-27, and for 1928; this diagram brings out with very striking clearness the tremendous importance of respiratory diseases as far and away the most outstanding cause of death; the mortality from plague is almost insignificant. The chief figures run for death rates due to: respiratory diseases 8.1, congenital debility and diseases of early infancy 2.4, tuberculosis 1.3, ague and remittent fever 1.1. The two peaks in the mortality curve for 1928 occurred in April, due to smallpox, and in November due to malaria. The figures for death rates by wards are somewhat untrustworthy, as so many patients die in hospitals without their residential addresses in the city being known.

Infantile mortality was 311 per 1,000 registered births, the lowest figure so far recorded. (This figure may seem amazingly high to those accustomed to European conditions, but it is raised by a special factor. So many women go to their homes outside the city for confinement that a very large number of births registered outside Bombay; these women then return to Bombay, and if the child dies in Bombay its death—but not its birth—is recorded in the vital statistics for the city.) Infantile debility, respiratory diseases, and convulsions head the list as the three chief causes of infantile mortality. Debility and prematurity are the chief causes during the first four weeks of life, respiratory disease during the remaining eleven months of infancy. Death rates vary from 332 among low caste Hindus, and 328 among Mahomedans, to 62 among Europeans. No less than 82.9 per cent. of infantile deaths occurred among families occupying one room or less, and the proportion of deaths to births varies inversely as the number of rooms occupied by the parents.

With regard to the prevention of infantile mortality, 10 municipal nurses are employed; they paid 41,461 visits during the year to chawls and tenements, attended 1,370 confinements, and verified 5,115 birth entries. The four municipal maternity homes—including the new Worli Home, which was opened in May, 1928—admitted 2,850 women for confinement. Two infant milk depots were opened during the year for distribution daily of pure milk at a minimal price.

The Infant Welfare Society made much progress, and its skilled midwives attended 1,040 confinements during the year.

Turning to the chief epidemic and other diseases, plague was insignificant during the year—death rate 0.2. The usual measures were in force. Smallpox (0.4) was less prevalent than usual. Cholera and influenza were notably on the down grade. Pulmonary tuberculosis still contributes an annual mortality of 1.2 per mille. Two anti-tuberculosis dispensaries are at work, and three special nurses are employed in visiting the homes of the patients who attend; a total of 1,828 patients was treated at the two dispensaries during the year. The Turner Municipal Sanatorium at Bhoiwada admitted 121 new patients during the year, and discharged 124, with, in addition, 4 deaths. Of those discharged in improved health there were 56 in stage I, 22 in stage II, and none in stage III; all four deaths occurred in stage III cases.

Malaria itself was registered as the cause of 295 deaths, but in all 1,431 deaths were registered as due to ague and remittent fevers. A very large volume of anti-malarial measures was carried out during the year, but the anopheline breeding sites in Bombay are extremely numerous; open wells, cisterns, fountains and tanks, tubs, gully traps, storm water entrances, tins, pools, cellars, and low lying depressions were all incriminated in considerable numbers during the year. In all 16,317 children were examined, and the spleen rates found to vary from 1.2 to 19.8, with a general average of 6.2. Parasite rates calculated from random samples taken in different wards by the malaria inspectors varied from 2.1 to 30.4 per cent. (These figures show that, although Bombay cannot be regarded as a hyperendemic zone, yet malaria constitutes one of the most troublesome and important public health problems in Bombay.) Admissions from British troops to the Colaba hospital were 972 in 1921 and 387 in 1922, before the commencement of reclamation anti-malaria measures; these measures were introduced at the latter date, and the admission rate had sunk to 129 per 1,000 in 1928. "Malaria," however, writes Dr. Sandilands, "is widely prevalent in the city."

That there is a vigorous anti-malaria policy in force, however, is shown by the figures on p. 26 of the report, which summarize in tabular form the work carried out during the year. With regard to the issue of drugs, 76 lbs. of quinine and 96 lbs. of cinchona febrifuge were supplied free through the municipal dispensaries to patients and others during the year.

Veneral diseases accounted for only 44 deaths registered during the year, but this is no measure of the incidence of these diseases in the community, and the special dispensary at Lamington Road, under Dr. Noronha, treated 2,942 patients during the year. This work is very heavy, and it included 789 injections of neo-arsenobillon and 1,262 of bismuth preparations, and the carrying out of 622 Wassermann tests. The incidence of gonorrhoea is almost twice that of syphilis, which is the lowest of the three veneral infections on the list.

Thirteen municipal dispensaries were open throughout the year to administer free medical relief. The attendances at these numbered 210,467, including 84,048 new cases. The special eye dispensary treated 1,281 new patients during the year.

For public health purposes, the city and island of Bombay is divided into 7 wards, 10 registration and sanitary districts, and 39 sections—each of the latter being in charge of an inspector, styled a medical assistant. There are also special staffs for maternity and child-welfare, milk and food inspection, and a veterinary section. The total quantity of milk consumed daily is 23,000 gallons, and as this works out at only 3.1 ozs. per head per day, it must be regarded as quite insufficient for a population, the great majority of whom are vegetarians. Of the milk consumed 78 per cent. comes from milch cattle stables within the city, 21 per cent. is imported by rail, and 1 per cent. by road. During the year 960 hawkers

importing milk by train were inspected; 268 of them were found to have no license, and 137 of them were carrying the milk in open cans without covers. The scheme for the abolition of stables inside the city and their transfer to rural areas outside Bombay has unfortunately been held up by legal difficulties.

With the completion of the new Tansa pipe line, the city as a whole is now provided with an adequate and constant water supply. The whole supply was chlorinated throughout the year, and no provision of any kind is made for filtration. The present sewer system is quite inadequate and the continuance of the old insanitary basket privies leads to a gravely insanitary system. The only satisfactory feature of present day conditions is that the Corporation pay a subvention of Rs. 100 to landlords for each privy converted into a water closet within three months of due notice having been received; and landlords are beginning to realize that this enhances the value of their property.

With regard to housing, financial considerations and the difficulty experienced in preserving a balance between the number of insanitary dwellings demolished and the number of new tenements provided to take their place has led to the postponement of action in a number of areas. Since the year 1898 the City Improvement Trust has provided 47,342 new tenements as against 32,522 tenements demolished.

The volume also includes minor reports in addition to that by Dr. Sandilands. Dr. P. T. Patel contributes a report on the working of the Arthur Road Hospital, and another on the Maratha Plague Hospital for the year. Smallpox was prevalent during the year, and reached its maximum with 140 admissions in March. Case mortality was 8 per cent. among the vaccinated as against 41 per cent. among the unvaccinated. There were 129 admissions for plague during the year; and anti-plague bacteriophage was under trial but gave disappointing results. The municipal laboratory was in charge of Dr. C. Coutinho, and carried out 5,599 examinations during the year. Thirty per cent. of samples of *ghi*, 26 per cent. of those of butter, and 20 per cent. of those of tea dust, were found to be adulterated. Full details of the results of water analysis are given in tabular form. Dr. K. N. Choksy reports on the vaccination work of the year. The total number of vaccinations performed was 35,643, and in primary vaccinations the success rate was 93 per cent. Ninety-three per cent. of the Haj pilgrims passing through Bombay during the year were vaccinated in Bombay before embarkation.

Correspondence.

CARBON TETRACHLORIDE, MERCK.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—My attention has been drawn to the article by Dr. S. C. Nag, entitled "Notes on the Use of Carbon Tetrachloride," published in your journal for December, 1929, which describes various toxic symptoms that in his cases arose after the administration of this drug. The discussion at the end of the article leaves it open to doubt whether these symptoms may possibly be attributed to impurities in the drug used. Since this latter was Carbon Tetrachloride "Merck," the whole matter was placed in the hands of my Analytical and Pharmacological Laboratories for comment.

They now report that in their opinion the toxic effects observed cannot possibly be attributed to the Carbon Tetrachloride "Merck." This preparation is manufactured to conform with the requirements of all pharmacopœias. Apart from this, it undergoes further tests to guarantee its complete freedom from chlorine, carbon disulphide, phosgene and other organic impurities; additional tests are made regarding its specific gravity and boiling point.

I should like to take this opportunity of referring your readers to Dr. Heraldo Maciel's article on "The Use of Carbon Tetrachloride as an Anthelmintic," which appears in E. Merck's *Annual Report*, 1929, Part 3.

Dr. Heraldo Maciel, who is Staff Surgeon in the Brazilian Navy (D. P. H., Rio de Janeiro), occupies such a position that he can speak authoritatively on this subject. He states:

..... "The innocuity which we have observed in the medicament we attribute mainly to the age of the majority of our patients (generally young men of from 16 to 30 years of age), to the small doses, and finally to the purity of the product which we use, namely necatorine or Carbon Tetrachloride extra pure 'Merck'....."

I may say, therefore, that the toxic effects, observed by Dr. S. C. Nag, must definitely be attributed to other causes.—Yours, etc.,

E. MERCK.

DARMSTADT,
17th February, 1930.

LIQUID EXTRACTS OF KURCHI.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In connection with my paper on "The Use of a Standardized Preparation of the total alkaloids of *Kurchi* bark in Amoebic Dysentery" in your issue for February, 1930, the following corrections should be made:—

(i) On p. 81, first column, line 20, the paragraph should read:—

"I had samples purchased in the bazaar of the preparations by Messrs. B. K. Paul, the Bengal Chemical Co., Messrs. Smith Stanistreet, The Union Drug Co., and Dr. Bose's Laboratory analysed with reference to their alkaloidal content, and the total alkaloidal content was found to vary from 0.214 to 0.128 per cent. (1928)."

These examinations were carried out on samples purchased in the bazaar, and the analyses were carried out in the middle of 1928. To-day in 1930 I am assured that the state of affairs is very much better. The watery extracts which were in use in 1928 are now not in use to any extent, and have been generally replaced by alcoholic extracts which are well up to standard strength. This is as it ought to be.

(ii) On p. 81, second column, line 18, please read "Campbell Medical School Hospital, Calcutta," and not "Carmichael Hospital" as stated.—Yours, etc.,

A. R. MAJUMDAR, M.B.

CAMPBELL HOSPITAL,
Calcutta, 6th March, 1930.

(Note.—With regard to the first correction, we believe that the paragraph as originally printed was what was sent in by our contributor. For the second mistake, we must take the blame for an editorial error. Dr. Majumdar's entire article had to be re-typed after correction before sending to press.—EDITOR, I. M. G.).

THE PURITY OF TUBE WELL WATERS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Lieut.-Colonel Clemesha's letter in your February issue on the above subject contains a suggestion of great value. We have been much puzzled in Rangoon by the bacteriological findings in tube well waters after heavy rainfall.

Lieut.-Colonel J. Morison, I.M.S., when in charge of the Pasteur Institute here, believed that most of our bacillary dysentery was due to contamination of the water supply. The main water supply of the town is from Hlawga Lake a reservoir some 14 miles from Rangoon. This supply is chlorinated, though the protection afforded by this measure appears to be reduced by leaks in the distribution system. Only a relatively small proportion of our supply comes from

tube wells, which are for the most part over 150 feet deep.

I am loath to believe that these wells have been to any great extent responsible for our bacillary dysentery outbreaks which occur principally in the fly breeding season, but, following up Lieut.-Colonel Morison's suggestion, Dr. Muekey and I have examined the tube well waters with the results noted in our article in your January issue.

Lieut.-Colonel Clemesha's theory appears to me the probable true explanation, and I am grateful to him for making it and hope to carry out a test on a cement grouted well during the present year. The well I propose to grout is one which is 168 feet deep, does not pass through an impermeable layer, and which has shown consistent evidence of pollution following rainfall, though the water is of a high standard of purity in the dry weather.—Yours, etc.,

G. JOLLY,

Lieut.-Colonel, I. M. S.

DEPARTMENT OF PUBLIC HEALTH, BURMA,
SECRETARIAT, RANGOON,
5th March, 1930.

COCONUT MILK AS AN ANTHELMINTIC.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—A European patient of mine who suffered from symptoms of cardiac distress sent me one day a dry specimen of an intestinal parasite of which he said he passed quantities at intervals. I only saw him again after a month or so, when I remarked his general physical improvement, and he told me of an unusual experience he had gone through. He said that shortly after consulting me, he was on tour and one day drank the water of a tender coconut. A day or so later he passed what, from his description of it, appears to have been a matted clot of an entire tapeworm.

My cook, who has a knowledge of preparing fresh infusions and "teas" from Indian herbs, has now on two occasions prepared a warm drink of coconut "milk" and common salt for children suffering from a bloated abdomen and such other symptoms of hookworm infection as anaemia and breathlessness. On both these occasions, although no definite examination of the stools could be made nor a specimen brought, the statement was made that the children were very much better after having passed a "handful" of tiny worms.

One's curiosity having been aroused, this remedy as an anthelmintic has been vouched for on more than one occasion. I shall be much obliged for the opinion of a food analyst, or, through the medium of your columns, for a scientific explanation of the peculiarly beneficial action of the water of the tender coconut, or the "milk" of the adult coconut in such cases.—Yours, etc.,

H. STOKES.

WESTCLIFF, KOTAGIRI, NILGIRIS,
SOUTH INDIA,
7th February, 1930.

"APHONIA AFTER QUININE ADMINISTRATION."

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In the January 1930 issue of the *Gazette* Dr. N. S. K. Iyer reports a case of aphonia following quinine administration.

Whilst I was in charge of a dispensary at Kalva in the Kurnool district in 1902, there came to me a Mahomedan boy of 8 years old, asking for a dose of purgative. I gave him, I remember, a dose of Pulv. Jalapæ Co., according to his age, at about 8 a.m. At noon on the same day his father brought him to me, complaining that the boy could not speak, although he was all right in all other respects. I wished to keep the patient under observation until the

evening, but, to satisfy the father, I gave him half an ounce of Aqua Chloroformi, with a request that the boy should be brought to the dispensary in the afternoon. When he came, I was glad to note that he was able to talk as usual. Subsequently I was informed by the compounder that the bottle contained plain water instead of Aqua Chloroformi.

Therefore a simple purgative can also produce "aphonia."—Yours, etc.,

S. A. JEGARAYA MUDALIAR, L.M.P.,

Civil Assistant Surgeon (retd.).

ST. ANTHONY'S COTTAGE,
COIMBATORE, SOUTH INDIA,
30th January, 1930.

MILK INJECTIONS IN SKIN DISEASES.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The treatment of eczema and psoriasis by intramuscular injections of milk deserves to be better known. I have recently treated a series of such cases by this method with very good results. The milk is sterilized by heating in a test-tube, and the injection given intramuscularly into the buttock, twice a week. I commence with a dose of 1 c.c., and increase the dose by 1 c.c., up to a dose of 5 c.c. Courses of from 6 to 16 such injections give very satisfactory results in such cases.—Yours, etc.,

RAM PROSAD,

Medical Officer.

SARSO DISPENSARY,
P. O. MANIGATHI, DAHANGA,
4th March, 1930.

Service Notes.

APPOINTMENTS AND TRANSFERS.

LIEUT.-COLONEL W. L. Harnett, M.B., F.R.C.S., I.M.S., Superintendent, Campbell Medical School and Hospital, is appointed to act temporarily as Professor of Clinical and Operative Surgery, Medical College, and Surgeon to the College Hospital, Calcutta, *vice* Lieut.-Colonel H. B. Steen, M.D., I.M.S.

Lieut.-Colonel J. S. O'Neill, M.C., I.M.S., Civil Surgeon, from Bareilly to Cawnpore.

Lieut.-Colonel B. E. M. Newland, I.M.S., Civil Surgeon, from Moradabad to Bareilly.

The services of Lieut.-Colonel G. T. Burke, M.D., I.M.S., are placed permanently at the disposal of the Government of the United Provinces, with effect from the 16th February, 1924.

The services of Major P. N. Basu, I.M.S., are placed temporarily at the disposal of the Government of the United Provinces, with effect from the date on which he assumes charge of his duties.

Major W. P. Hogg, D.S.O., M.C., I.M.S., an Officiating Agency Surgeon, is posted as Agency Surgeon in Bhopal, with effect from the 17th February, 1930.

In the previous orders placing the services of Major M. Fazluddin, O.B.E., I.M.S., temporarily at the disposal of the Government of the Punjab for employment in the Punjab Jail Department for the words "with effect from the 1st January, 1930," read "with effect from the 20th January, 1930."

Major H. E. Murray, M.D., M.Ch., I.M.S., is appointed as Civil Surgeon, Bakarganj, with effect from the forenoon of the 21st March, 1930, *vice* Major S. A. McSwiney, I.M.S., granted leave.

Major W. C. Spackman, F.R.C.S.E., M.B., B.S. (Lond.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), D.T.M. (Lond.), I.M.S., is appointed as Officiating Professor of Midwifery and Gynaecology, Grant Medical College, and Superintendent, Bai Motlibai and Sir D. M. Petit Hospitals, during the absence on leave of Lieut.-Colonel Hamilton.

Captain D. P. Bhargava, M.B., F.R.C.S.E., I.M.S., whose services have been temporarily placed by the Government of India at the disposal of the U. P. Government, to Agra as Principal, Medical School.

Captain W. H. Critien, I.M.S., is appointed to officiate as an Agency Surgeon and is posted as Medical Officer and ex-officio Vice-Consul, Sistan, with effect from the 5th February, 1930.

LEAVE.

Major-General G. Tate, M.B., K.H.S., I.M.S., Surgeon-General with the Government of Bengal, is granted, preparatory to retirement, leave on average pay for two months and four days combined with leave on half average pay for three months and 28 days, with effect from the 15th March, 1930.

Lieut.-Colonel W. J. Simpson, I.M.S., an Agency Surgeon, is granted leave on average pay for 6 months combined with leave on half average pay for 2 months, with effect from the 17th February, 1930.

Lieut.-Colonel A. F. Hamilton, M.B. (Lond.), F.R.C.S. (Eng.), I.M.S., Professor of Midwifery and Gynaecology, Grant Medical College, and Superintendent, Bai Motlibai and Sir D. M. Petit Hospitals, is granted leave with effect from the 22nd March, 1930, or subsequent date of availing on average pay for two months and eighteen days followed by such leave on half average pay as will bring the total period of leave to eight months.

Lieut.-Colonel H. Ross, C.I.E., O.B.E., I.M.S., Civil Surgeon, Cawnpore, leave on average pay for twenty-three days followed by leave on half average pay for eleven months and seven days (total twelve months), with effect from 20th March, 1930, or the date of availing.

Major S. A. McSwiney, I.M.S., Civil Surgeon, Bakarganj, is granted leave for eight months, with effect from the 18th March, 1930.

PROMOTIONS.

The King has approved the promotion of Major D. F. Murphy, M.C., M.B., F.R.C.S.E., I.M.S., to the rank of Brevet-Lieut.-Colonel, with effect from the 1st January, 1930.

Captain to be Major.

E. T. N. Taylor, M.B. Dated 20th February, 1930.

Lieut. to be Captain (Prov.)

M. G. Kelly. Dated 7th March, 1930.

RETIREMENTS.

Subject to His Majesty's approval, Lieut.-Colonel H. H. Broome, C.I.E., M.B., F.R.C.S., I.M.S., has been permitted to retire from service from the 6th March, 1930.

I. M. S. DINNER.

THE Annual Dinner of the Indian Medical Service will be held in London at the Trocadero Restaurant on Wednesday, the 18th June, 1930. Full particulars can be obtained from the Honorary Secretaries, Indian Medical Service, Annual Dinner, 31, Wimpole Street, London, W.1.

NOTES.

"THE ECLIPSE SPRAYER."

THE disinfection of hospital wards, operating theatres, living rooms, theatres, cinema halls, and the like by spraying is now a universal practice. Yet many types of hand sprayers are unsatisfactory; intricate parts are apt to get out of order, the bucket type of machine has to be carried about, and "back-wash" is often troublesome. Some machines are too heavy; several leave the operator with only one hand free to spray, the other being used to carry the container.

A firm at Home which has paid especial attention to this problem for some years is the Eclipse Spraying Co., Ltd., Rawlings Road, Bearwood, Smethwick, England, and their "Eclipse No. 1 Sprayer" gets out of the rut of following stereotyped patterns, and is both ingenious and cheap. In this the spraying portion of the apparatus is complete in itself: the solution

used for spraying is placed in a bucket or similar container, the solution is drawn from the container by suction action, and up to 200 feet of hose can be used. Both hands of the operator are left free, and the first stroke on the sprayer draws in the fluid from the container, whilst the second ejects it in spray form. Spare "lances" may be had to increase the distance between the actual pump and the nozzle, whilst spraying can be stopped instantaneously by a slight sharp pull back of the piston rod. The apparatus is especially suitable for lime-washing and creasote spraying, whilst veterinary workers will be interested in the modifications for cattle drenching and injecting. The complete No. 1 outfit costs only 30s.

A modification of this sprayer is the "Eclipse Satchel Vaporizer," which is specially designed for hospitals, sanatoria, cinemas, etc. In this the satchel containing the solution is hung from the operator's right shoulder, like a military haversack, leaving both hands free for operating the spray. This is issued in two sizes: for 4 pints at 30s. and for 8 pints at 33s.

The uses to which such instruments can be put are almost innumerable, whilst the firm in question is a leading one in the study of this subject, and the production of new and suitable apparatus. The Indian agents are Messrs. Barlow & Co., P. O. Box No. 49, 37, Strand Road, Calcutta.

"ANTIVIRUSES BIOTHÉRIB."

IN connection with the note on p. 60 of our issue for January, 1930, on a staphylococcus antivirus, we have received a letter from Messrs. G. Loucatos, P. O. Box No. 783, Shushtary Building, 15-A, Elphinstone Circle, Bombay, drawing attention to the fact that for the last six years they have issued five kinds of antivirus, as agents for La Biothérapie, Paris. La Biothérapie, Paris, are the makers of Bilibaccine, under the direct personal control of Professor Besredka himself, who also supervises the manufacture of their Antiviruses Biothérin.

These viruses have been the subject of long and exacting tests under scientific control, in both clinical and practical fields, and have recently been adopted officially by the French Government by the Ministry for the Colonies for use in all French colonial hospitals and infirmaries. The antiviruses stocked, which are sterile filtrates of broth cultures, are as follows:—

Antivirus	Biothérin.
Streptococcic	"
Staphylococcic	"
Strepto-Staphylococcic	"
Coli-bacillary	"
Puerperal	"

Clinical reports from French hospitals report the special value of these preparations in puerperal sepsis, boils, phlegmons, osteomyelitis, anal fistula, folliculitis of confluent type, blepharitis and conjunctivitis, and other septic conditions. A small brochure, issued from Paris, gives details of cases reported, and instructions for the use of these Antiviruses Biothérin. This may be obtained on application to Messrs. G. Loucatos.

"ELIXOID" EPHEDRINE COMPOUND.

AN elixir agreeable to the palates of children and fastidious adults is now issued by Burroughs Wellcome & Co. under the name of "Elixoid" Ephedrine Compound. The value of ephedrine in asthma, hay-fever and other catarrhal conditions of the nose and naso-pharynx is now established, and its usefulness in mild and moderate cases of whooping-cough is fully recognized. "Elixoid" Ephedrine Compound is prepared with the pure lævo-rotatory alkaloid and is an acceptable means of administering ephedrine to children and to adults who prefer fluid medicine.

Issued in bottles of 4 fluid ounces.

A NEW VARICOSE VEIN CLIP.

THE spring clip shown in the accompanying illustration has been designed by Messrs. Down Bros., Ltd.,

21 and 23, St. Thomas's Street, London, S.E.1, at the suggestion of Mr. R. Davies-Colley, C.M.G., M.Ch., F.R.C.S., to take the place of an assistant in the operation of treatment of varicose veins by injection.

It consists of two padded metal plates connected by a horseshoe spring, which, when applied over the site of an injection, exerts sufficient pressure to prevent circulation through the vein while subsequent punctures are being made in other parts of the vein.

This clip will be of interest to many practising surgeons in India, we believe.

A MODIFIED FARABEUF RASPATORY.

The illustration below shows a modified form of Farabeuf's raspatory made for Lieut.-Col. J. N. Duggan, I.M.S., by Messrs. Down Bros., Ltd., 21 and 23, St. Thomas's Street, London, S.E.1.

"The standard form of rugine designed by Farabeuf of Paris for use on the long bones was found to bring the hand somewhat inconveniently near the work" writes Col. Duggan, "while the longer rugines designed by Pierpoint and Mitchell are rather heavy for fine work round the orbit. It is thought that the rugine illustrated above will be found convenient for the delicate and precise work which falls to the lot of an ophthalmic surgeon."

"DIGINUTIN."

A New B. W. & Co. Digitalis Preparation.

"DIGINUTIN"—a new Burroughs Wellcome & Co. product—is a stable solution of the total glucosides of digitalis leaf free from inert extractive matter. Specimens biologically tested after storage for more than twelve months have shown no diminution in activity and there seems to be no reason why the solution should not retain its full potency for many years.

It is not suggested that "Diginitin" should replace "Tabloid" Digitalis Leaf, but, being a stable solution, it may be preferred by some practitioners to the tincture. Compared even with preparations of the dried leaf, the new product offers certain advantages. Being in solution it may be expected to produce a more rapid response than the leaf, owing to more rapid absorption. Further, the physiological standardization of the solution is more accurate, owing to the absence of inert vegetable matter.

The potency of "Diginitin" is adjusted to that of the B. P. tincture and is controlled by physiological tests.

Clinical reports indicate that even after long keeping it is uniformly active, reliable and equal in effect to equal doses of the fresh official tincture.

Issued in bottles of 1 fl. oz. and 8 fl. oz.

NUTRITION.

Nutrition is a new small trade journal issued by the makers of Glaxo, of which we have received a recent copy, Vol. 1, No. 3. It contains a good deal of interesting information with regard to recent advances in modern dietetics and vitamin therapy. The editorial in this issue reviews recent advances in connection with the synthesis of thyroxin, insulin, and the use of old filtered broth cultures in the local treatment of bacterial infections. An article of special interest is one of the uses of vitamin D and calcium in delayed union of fractures. These are given hypodermically, the calcium being in colloidal form, and the emulsion made with olive oil. "Colloidal calcium with ostelin ampones." Five cases are quoted where results were excellent. A further use for the same preparation is in the treatment of early cases of pulmonary tuberculosis, where much improvement may result.

The Indian agents for Glaxo are Messrs. H. J. Foster & Co., Ltd., P. O. Box No. 202, Bombay.

ELECTRO-MEDICAL APPARATUS.

An interesting catalogue of electro-medical apparatus which we have recently received is one from Messrs. Newton & Wright, 471/3, Hornsey Road, London, N. 19—their publication No. E/29. This does not deal with ultra-violet and diathermy apparatuses, which are dealt with in a separate catalogue. The present catalogue, however, will be of interest to the general practitioner; types of galvanic and faradic batteries are described and listed; a universal machine for general electro-medical work, sinusoidal apparatus, vibrators for massage, electrodes and accessories, a Bergonie apparatus, and local and general heat and light baths.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints gratis, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters. Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box No. 51, Calcutta.

Annual Subscription to "*The Indian Medical Gazette*," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

STUDIES IN UNTREATED MALARIA.

I. A CASE OF EXPERIMENTALLY INDUCED QUARTAN MALARIA.

By R. KNOWLES,

LIEUTENANT-COLONEL, I.M.S.,

Professor of Protozoology,

and

ASST. SURGN. B. M. DAS GUPTA,

Assistant Professor of Protozoology,

Calcutta School of Tropical Medicine and Hygiene.

INTRODUCTION.

DESPITE the immense amount of research work on malaria during the present century, a little reflection will show how numerous and important are the gaps in our knowledge with regard to this disease. Thus the following are but a few of the many problems with regard to malaria which await solution:—

1. What is the natural death rate in untreated cases of malaria? No figures that we have had access to give any information on this point. The latest available *Annual Report of the Public Health Commissioner with the Government of India*—that for 1927—states that 3,451,454 deaths occurred from fevers in the population of 241,471,383 for which returns of vital statistics are received; a death rate of 14.22 per mille. Nearly all of this mortality was due to malaria, since relapsing fever only affected a few restricted areas, deaths from enteric fevers numbered less than 12,000, and so well is kala-azar now controlled by treatment that only 14,917 deaths from this disease were recorded in British India in 1927.

The corresponding admissions for malaria to hospitals and dispensaries in the British provinces totalled 8,398,775 in 1927, but this must represent only a small fraction of the total incidence of the disease, which must be placed at some six or seven times this figure. The state of affairs with regard to the dispensary "treatment" of malaria in India has been dealt with in faithful detail by Proctor (1927). Forty-eight per cent. of 698 cases observed in a rural area only attended a dispensary once, and only 20 per cent. put in two attendances. If the patient brought a bottle with him he received three doses of quinine mixture; if he brought no bottle he received only one dose. It is probable that most persons who suffer from malaria in India get one or more doses of some medicine or another; but in the vast majority of cases this is represented by some indigenous country medicine which has no lethal action whatever on the parasites. We doubt whether more than one in every five hundred patients who contract malaria annually in India receives a sufficiently thorough and

prolonged course of quinine treatment to eradicate the infection from his system. On adding together the figures for the distribution of quinine and cinchona febrifuge for the different provinces given in the same report, we find that less than 30,000 lbs. was distributed during the year, or approximately 432 million grains. This would represent a consumption of less than $1\frac{1}{2}$ grains per head per annum for the whole population of India and Burma. If we put down the total incidence of malaria cases per annum at about 50 million a year, this would represent only an average of 8.6 grains per case by way of treatment.

It will be seen from these figures how impossible it is to arrive at the natural case mortality in malaria. For *treated* patients figures are of course available. The biggest collection that we have come across is that quoted by S. P. James (1922, p. 1631) from returns by the Sanitary Commissioner with the Government of India. It is as follows:—

Years.	Class of patients.	Cases treated in hospital.	Case mortality per cent.
1903—1907	British troops ..	63,597	0.16
	Indian troops ..	144,728	0.42
	Prisoners ..	189,534	0.36
1898—1907	Wives of British soldiers.	3,042	1.0
	Children of British troops.	5,128	1.63

It is a well known fact that malaria is a more fatal disease in children than in adults, and that debilitating conditions and intercurrent infections may raise the malarial mortality, whilst in such terrible epidemics as that which swept the Punjab in 1908 the case mortality may be excessive. In ordinary endemic malaria however in untreated patients, we doubt whether the natural case mortality is much higher than 2 per cent. In other words some 49 out of every 50 untreated patients recover spontaneously from their attack of malaria.

What is the mechanism of this recovery? It is one of the most fundamental, but unanswered, problems in malariology, and a lifetime of study would be too short a period to devote to it. Christophers (1924, 1925) in his classical study of malaria in the Singbhum district has shown how the child community in a hyperendemic area gradually acquires immunity (or tolerance) to malaria with increasing age, whilst several other observers have commented on the same phenomenon. What we wish to know, however, is the mechanism by which immunity (or tolerance) is acquired in the individual. There are theories enough in the literature, but, as far as we

know, very little direct experimental observation on this point.

2. What are the relative intensities in infections with *P. vivax*, *P. malariae*, and *P. falciparum* respectively? Also what is the febrile threshold in infections with these three species? Ross and Thomson (1910) have supplied a partial answer to the latter question, but much further study of it is wanted.

3. We are very ignorant with regard to gametocyte production by the three species of parasite. When do gametocytes first appear in the peripheral blood? Some authors state that they appear late in the disease—some 8 to 10 days after the first rigor; others that they may appear quite early, at about the third or fourth day after the first rigor, or even earlier. What are the factors which lead to the production of gametocytes? How does their number correlate with the schizogony cycle? The best paper dealing with this subject that we know is that by Sinton (1926); but again further work is wanted.

4. A full study of the morphology of the malarial parasites by good cytological methods is badly wanted. We are even ignorant at present as to whether schizogony occurs by mitosis, as stated by Schaudinn many years ago, or by amitosis. Further, only when such a careful cytological study has been carried out, will it be possible to state definitely whether one or two species of parasite are included under the name *Plasmodium falciparum*.

5. The exact relationship of the schizogony cycle of the malaria parasites to the temperature chart was the subject of much early work by the Italian pioneers. In view, however, of the findings by S. P. James (1926, 1926a) with regard to the difference between primary and relapsing benign tertian malaria, a re-investigation of this problem is called for.

Methods and Technique.

It was a consideration of these and other allied problems that led us some nine months ago to completely alter our methods of study of malaria at the School and to make a special study of untreated cases. This was made possible by the fact that some of our colleagues at the Calcutta School of Tropical Medicine from time to time have treated cases of neuro-syphilis, and even of tertiary syphilis, by experimentally induced malaria. The course of untreated malaria can be very well studied in such patients. The case of experimentally induced quartan malaria to be described belongs to this group; the patient was under the care of Dr. Shivapada Bhattacharjee, M.D., Acting Professor of Tropical Medicine at the School, and we are most grateful to him for the full facilities which he gave us for studying the case.

With regard to technique, the parasite counts have all been carried out by the method advo-

cated by Sinton (1924). We have found this method a most admirable one. The original suspension of fowl's red blood corpuscles was diluted 1:8, and counted sixteen times; the figures ranged from 24,040 to 28,580 per c.mm. at the extremes, with a mean at 26,558 per c.mm. This was next diluted down to a strength of 10,000 corpuscles per c.mm. The suspension, which is kept in an ice chest, has kept in perfect condition since it was prepared nine months ago.

In staining the films of mixed suspension of fowl's corpuscles and patient's blood, the use of Leishman's stain is rather apt to lead to deposit and difficulties in counting. The suspension contains a trace of mercuric perchloride and is definitely acid; hence it is better to use an alkaline stain. Details are as follows:—

- (1) The film is fixed with methyl alcohol of pH 6.8.*
- (2) Distilled water rendered very slightly alkaline, pH 7.2, by the addition of N/10 NaOH is used. The film is washed with this.
- (3) Stain for 20 minutes with Giemsa's stain; strength 1 drop to 1 c.c. of distilled water of pH 7.2.
- (4) Wash with distilled water, pH 7.2.
- (5) Allow the film to dry in air. Do not blot.

This technique gives a nice clean film, fairly deeply stained. The counts have all been carried out by the senior author (R. K.) with a binocular Leitz microscope, fitted with an apochromatic 1/12th inch oil immersion lens. In almost all instances the number of parasites corresponding to 250 nucleated red corpuscles has been counted; but occasionally when the infection was extremely heavy, counts have had to be made against 100 nucleated red cells.

Each parasite is entered separately on the record for each day's count. In order to subdivide the schizogony cycle into its constituent elements we have recorded the parasites under the following headings:—

- (a) Free merozoites, unattached to red corpuscles. These are only seen in close proximity to the time of rigor.
- (b) Rings, still preserving the ring outline, and with the vacuole present. The "ring" is of course a young trophozoite.
- (c) Growing trophozoites, with chromatin undivided.
- (d) Schizonts, showing division of the chromatin.
- (e) Mature rosettes in which the merozoites have developed fully, and are distinguishable as different individuals.
- (f) Gametocytes.

The Bass cultures have all been carried out by the modification of Bass' technique advocated by J. G. and D. Thomson (1913, 1913a).

* When we say that the pH of pure methyl alcohol is 6.8, we mean that the colour developed by adding 0.25 c.c. of 2 per cent. phenol red to 10 c.c. of methyl alcohol is the same as that shown by adding the same amount of indicator to 10 c.c. of a phosphate Sorensen buffer of pH 6.8.

(Almost all cases of malaria submitted to the department for laboratory diagnosis are now examined culturally, as it is only in this way that the true frequency of mixed infections can be arrived at, and very scanty infections not overlooked.)

It is obvious that it will take several years before sufficient observations have been collected for a full and detailed analysis in memoir form. For this reason we propose to publish from time to time in this journal the more interesting or clinically important of the cases observed, reserving a more detailed study of the whole subject for final analysis when sufficient data have been accumulated. A previous series of seven cases has previously been submitted for publication elsewhere.* The present case constitutes the eighth of the series.

It is only when one comes to study malaria by enumerative and cultural methods that one realises what a delicacy and precision of observation such methods afford. Sir Ronald Ross (1911, *Prevention of Malaria*, p. 651) has well emphasised the necessity for statistical and enumerative methods in the study of disease, both in the community and in the individual. "As a matter of fact," he writes, "all epidemiology, concerned as it is with the variation of disease from time to time or from place to place, must be considered mathematically, however many variables are implicated, if it is to be considered scientifically at all. . . . And the mathematical method of treatment is really nothing but the application of careful reasoning to the problems at issue. . . . The application of mathematics to epidemiology and even pathology has suggested itself to me (and perhaps to others) for many years; and when I came to write my Mauritius report (1908), I found myself driven to make some attempt in this direction. I suggested there the name *pathometry*, which can be applied to all mathematical study of infectious disease whether in the individual or in the community."

Details of the Case.

J. R., Hindu male, aged 35, peon, was admitted to hospital on the 23rd January, 1930, complaining of inability to walk properly, a waddling gait and difficulty in micturition, the duration of the symptoms being six months. Ten months previously he had had a skin eruption, and the Wassermann reaction—tested in the Imperial Serologist's Department—was strongly positive. The case was thus clearly one of syphilitic paraplegia. There was no fever from the date of admission until March 5th. A Bass culture on the 23rd January gave negative results. The spleen and liver were not enlarged.

It was decided to test the effect of induced malaria on the condition present.

* Knowles and Senior-White. "Studies in the Parasitology of Malaria." The memoir deals chiefly with the geographical, regional and seasonal distribution of the three species of *Plasmodium* in man. Accepted for publication as No. 18 of the *Indian Medical Research Memoir Series*, supplementary to the *Indian Journal of Medical Research*.

30th January.—A patient presented himself in the out-patient department, suffering from quartan malaria. Examination of blood films from this patient showed scanty rings, trophozoites, and schizonts of *Plasmodium malariae*. A culture by Bass' method showed *P. malariae* present (only). From this donor 1½ c.c. of blood was withdrawn and injected subcutaneously into patient J. R.

31st January to 16th February.—Daily blood films from patient J. R. were examined but no parasites found. On February 15th a Bass' culture of J. R.'s blood gave negative results.

This first inoculation therefore appeared to have failed.

17th February.—In the meantime the donor had been kept off treatment; he continued to attend the laboratory and his blood was examined from time to time.

On the 17th February 5 c.c. of this donor's blood was given to the patient J. R. The injection was given intramuscularly, and, as the needle was withdrawn, partly subcutaneously. Examination of films from the donor's blood showed a fair number of rings and growing trophozoites, and scanty schizonts and gametocytes of *P. malariae* present.

18th February.—One trophozoite present in a blood film from J. R. (This was presumably an injected parasite, as the films subsequently became negative.)

19th February to 3rd March.—No parasites found.

4th March.—Very scanty trophozoites and gametocytes of *P. malariae* present.

5th March.—The temperature rose in the evening to 99°F., but dropped during the night.

6th March.—Blood films showed rings, trophozoites, and schizonts of *P. malariae* present. Counts commenced. These were thereafter continued daily (with the exception of Sundays, when the laboratories are closed).

The patient had his first rigor at 6 p.m. that evening, the temperature going up to 103°F.

The subsequent course of the disease was as shown in the temperature chart (Chart 1). The daily counts were as shown in Table I. Chart 2 shows the correlation between the temperatures (as taken at the moment the blood was taken for the count), the total parasite count, and the gametocyte count per c.mm. An interesting clinical feature of the disease was that, with one exception, the rigors invariably occurred after 6 p.m.

On March 28th at 4-15 p.m. the temperature was 100°F., and the total parasite count 8,550 per c.mm. At 9-30 the same evening the patient had a rigor, and the temperature rose to 104.6°F. by 2 a.m. on the 29th. As the patient was now in rather a bad condition a single dose of 10 grains of quinine sulphate in solution was given. The effect on the count will be seen in Table I. The count dropped to 960 parasites per c.mm. the next morning, and to 520 per c.mm. the day after.

Regular quinine treatment, 10 grains twice daily in solution, was commenced on the morning of March 31st.

5th April.—After 120 grains of quinine in solution, thin and thick blood films failed to show parasites.

9th April.—After 200 grains of quinine in solution, Bass culture negative.

30th April.—Bass culture negative, sixteen days after cessation of all quinine treatment.

Patient discharged from hospital. He is convinced that the condition of spastic paraplegia is very much improved, but there is little objective sign of improvement. So much fuss has been made about him that the improvement appears to be due chiefly to psychic suggestion.

Discussion.

The case presents many features of interest, both with regard to experimentally induced malaria in man, and to the life cycle of *Plasmodium malariae*.

CHART 1.

1. *Intensity of the Infection.*—In the first place the intensity of the infection is very remarkable for a case of quartan malaria. At 4 p.m. on March 6th the temperature was 98.2°F., and the count 320 parasites per c.mm., the only parasite forms encountered being maturing schizonts. The first rigor followed at 6 p.m. the same evening. Thus the attack of quartan malaria commenced, so to speak, as a pure strain infection. The schizonts presented from 5 to 10 bits of chromatin apiece, and all clearly belonged to the same generation of parasites. From such a beginning, one would have expected a quartan fever of mathematical regularity to follow.

By 1 p.m. on the 22nd March the parasite population had reached a figure of 43,600 per c.mm., seven hours before a rigor. Such a count is almost incredible for a quartan infection, yet it was but little higher than the figure of 32,600 per c.mm. at 10-30 a.m. on March 19th, half an hour before a rigor. In general it will be seen from the table that the parasite population tended to fluctuate between 6,000 and 10,000 per c.mm. Correlated with this finding was the fact that the patient suffered fairly severely. He was at no time in any danger, but he was a very sick man.

By way of contrast to this case, one may quote the findings in a naturally contracted case of quartan infection. As follows:—

Case 2.—J. N., Hindu male, aged 26, cultivator, was admitted to hospital on the 21st July, 1929, and gave a history of having had attacks of fever on and off for the preceding five months. He had been treated by urea-stibamine injections without effect. The liver was enlarged to 1½ finger-breadths below the costal margin, and the spleen to 4 finger-breadths. The patient was markedly anemic. Thin and thick blood films and a Bass culture taken on admission showed *P. malarie* (only).

22-7-29. 98°F. 565 parasites per c.mm.; trophozoites and gametocytes.

23-7-29. 97.6°F. (Rigor an hour later.) 700 parasites per c.mm.; mostly mature schizonts.

24-7-29. 97°F. 50 per c.mm.; trophozoites.

25-7-29. 99.6°F. Count less than 45 per c.mm.

26-7-29. 100°F. 367 per c.mm.; trophozoites and schizonts.

As there seemed to be no evidence that spontaneous cure was taking place, this patient was now put on to alkalies and quinine.

The two cases present a complete contrast to one another. In J. R.'s case, the quartan fever (as will be discussed later) was almost certainly a primary attack; in the case of J. N. the condition present was one of chronic relapsing quartan infection. In the former the counts reached a very high figure, and the disease showed no tendency towards spontaneous cure during the 24 days that the malaria was allowed to run its course; in the latter a condition of chronic relapse was associated with low counts with a tendency towards reduction of the parasites.

J. R.'s case enables one to understand the occasional reports of extremely severe, and sometimes fatal outbreaks of quartan malaria, by workers in the Dutch East Indies, such as that by Schuurman and Schuurman-ten Bokkel Huinink (1929) with regard to the marshy

zone of Kali Rawan on the south coast of Java. It is clear that sometimes quartan malaria may become a very severe disease.

2. *Mechanism of Parasite Destruction.*—Despite the intense severity of the infection, however, the counts make it clear that there

											Bass culture negative 16 days after cessation of quinine treatment.

CHART 2.

was an enormous destruction of parasites going on in this patient's blood. At 4 p.m. on March 6th the count was 320 per c.mm., and this was followed by a rigor the same evening. Assuming that each schizont gives rise to about 8 merozoites, this should have led to a parasite population of about 2,560 per c.mm. the next day; whereas the actual count was only 1,640 per c.mm.

The count at 10-30 a.m. on March 19th is of special interest in this connection. The film showed no less than 92 per cent. of mature rosettes or free merozoites, and a rigor occurred half an hour after it was taken. The number of merozoites present was 117,000 per c.mm. of blood. Were no merozoites to undergo destruction, this should have led to 117,000 growing trophozoites the next day. The actual count the next day, however, was 5,840 parasites per c.mm.

In other words at this schizogony cycle 117,000—5,840 merozoites per c.mm. were destroyed on rupture of the mature rosettes; or 111,160 merozoites per c.mm. This represents 111,160/117,000ths of the infection, or 95 per cent. of the parasite population present. Although the malaria infection was at this stage a gradually progressive one and the patient was very ill, yet his natural powers of resistance were such that his system could kill off 95 per cent. of the parasite population at each schizogony cycle. In cases of malaria undergoing spontaneous cure or resolution, the percentage destruction of parasites must be at an even higher level. If it were not for this natural resistance to malaria, there would be no population left in the tropics.

What is the exact mechanism of this destruction of parasites? The counts in Table I suggest that it is only during the free merozoite stage that parasites are destroyed. Once they enter within the red corpuscles they are safe until the next schizogony cycle matures; and consequently the counts in the intervals between the rigors for one and the same schizogony cycle tend to remain at about the same level.

In culture the destruction of parasites is confined to the free merozoite stage, and takes place by phagocytosis by the polymorphonuclear leucocytes. We were not aware of this until we saw Thomson and Robertson's recently published *Protozoology, a Manual for Medical Men*. In Plate III of that book, fig. 24, there is shown a polymorphonuclear leucocyte containing the merozoites and hæmozoin pigment of two rosettes of *P. falciparum*. Fig. 1 is a reproduction of this sketch by Thomson and Robertson in black and white.

When we first saw this sketch, we were frankly incredulous. The authors do not mention from what source it is taken, but we presume that it must be from a culture. Subsequently, however, we have often seen the same phenomenon in cultures. It can be observed readily by taking films from the culture at

the moment when the majority of rosettes are bursting and liberating their merozoites.

We have never seen the same phenomenon in blood films from man, however, and we very much doubt whether phagocytosis of the merozoites occurs in man. We have shown the

Fig. 1.—Polymorphonuclear leucocyte containing two malignant tertian schizonts.
(After Thomson and Robertson, 1929. *Protozoology*, Plate III, fig. 24.)

sketch by Thomson and Robertson to most of the well known malariologists of India, and to the members of the Malaria Commission of the League of Nations when they visited Calcutta last October, and none of them had ever seen this phenomenon in blood films from man. Of course it is well known that when the rosettes burst, the liberated hæmozoin is engulfed by the large hyaline mononuclear leucocytes, and carried by them to the internal viscera, but, as far as one knows, no author has suggested that merozoites are ingested by the leucocytes of any type. D. Thomson (1914) has a sketch showing ingestion of merozoites by endothelial cells of the spleen, the material having been obtained at a post-mortem examination. On the other hand Knowles, Acton and Das Gupta (1923), in a series of spleen punctures carried out on patients with chronic and relapsing malaria, failed to find any evidence of phagocytosis, either by leucocytes or by the endothelial cells; what was present were parasites in all stages of lysis and dissolution, the chromatin undergoing karyolysis and karyorrhexis, and the cytoplasm becoming progressively more and more vacuolated, until finally the parasites disintegrated, leaving behind nothing but free hæmozoin. (The colour plate with which it had been intended to illustrate that paper of 1923 was unfortunately lost; but the findings present all pointed to lysis of the parasites, rather than to phagocytosis.)

The exact mechanism of parasite destruction requires much more study than it has received hitherto in the malaria literature. Tentatively we would suggest that such destruction only takes place during the free merozoite stage; that it is probably due to the production of lysins in the plasma, though possibly phagocytosis by the endothelial cells may also play a part.

3. *The Fever of First Invasion in Quartan Malaria* appears to be a rather irregular one. It shows a tendency towards quartan periodicity, but is much more irregular than is the

periodicity when the infection is well established.

We have every reason to believe that this was the first attack of quartan malaria from which this patient had ever suffered. The patient is a resident of Muzafferpore, and had only come to Calcutta a month and a half before his admission to hospital. It is not likely that he could have contracted quartan malaria in the former station, for the general incidence of quartan malaria in the United Provinces is only 3.9 per cent. of the malaria present.* He stated that he had been free from fever during the previous ten years, and he was completely afebrile during the first 36 days of his stay in hospital before the onset of the induced fever.

Further, the Bass cultures of January 23rd and February 15th both gave negative results. Of course one cannot absolutely exclude previous malaria infection in any patient residing in the plains of India, but we have every reason to believe that this patient had never previously suffered from quartan malaria.

We may take the rigor at 6 p.m. on March 6th as the starting point, so to speak, of one schizogony cycle, as the film taken at 4 p.m. that afternoon showed nothing but maturing schizonts. Then—

Rigors should have occurred on March.	Rigors actually occurred on March.	Interval in hours.
6th	6th	..
9th	9th	75
12th	12th	71
15th	13th	24
18th	16th	70
21st	18th	65
24th	22nd	81
27th	25th	71½
30th	28th	74

Now James (1926, 1926a) has drawn attention to the difference between primary benign tertian malaria, as induced in mental patients by bites of infected anophelines, and relapsing benign tertian malaria or re-infection. In primary benign tertian malaria in persons who have never had malaria before, the incubation period after the mosquito bite was from 7 to 23 days, and the patient then developed the fever of the "initial stage" which lasted from 2 to 5 days. This is at first a gradually increasing fever, at first sub-continuous or irregularly remittent, but towards the end of this stage always intermittent. There are no rigors during this period, and its termination is sometimes shown by an intermission lasting 24 or 48 hours. The initial stage is followed by the developed stage; in 80 to 90 per cent. of cases this is not a fever of tertian periodicity, but a fever of quotidian periodicity with a daily rigor. This lasts for ten days or longer. It is followed by the terminal stage. In this the type of fever again changes, and becomes the

typical benign tertian fever of the textbooks with tertian periodicity and a rigor every 48 hours. At a future date, should the patient have a relapse or a re-infection, the initial stage and the stage of daily rigors are not shown; the fever is a typically tertian one. James explains this phenomenon of the initial stage and the daily rigors by a lag in development of some of the parasites.

A study of Charts 1 and 2 shows a somewhat similar trend. The fever at first tends to be irregular, and rigors occurred at an interval of only 24 hours. Later, as the fever became more established, so to speak, the temperature chart and the counts showed a much more marked quartan periodicity.

The correlation between the counts and the temperature chart is much less exact than might have been expected (Chart 2), but this is perhaps because the counts were not carried out frequently enough. The absence of counts on the three Sundays in March is unfortunate, and it is clear that in future studies on such cases counts will have to be taken with due regard to the temperature chart. The correlation of high counts with the approaching rigor, however, is well seen in the counts of March 19th, 22nd, and 25th.

4. Notes on the Schizogony Cycle of *Plasmodium malariae*.

A study of the relative percentages columns in Table I shows many features of interest.

Free merozoites were only encountered within half an hour of the rigor, and it would appear that the free merozoite stage only lasts for a very short period—probably not for more than an hour or two.

The duration of the ring form, with the vacuole still in evidence, is not very prolonged. It will be seen that rings were a prominent feature of the counts on—

March 10th at 13½ hours after the rigor.

March 20th at 24½ hours after the rigor.

March 26th at 16 hours after the rigor.

March 29th at 13½ hours after the rigor.

Far and away the commonest phase of the parasite encountered is the growing trophozoite phase before schizogony sets in, and of these forms (in this particular instance) the "equatorial band" forms were much the commonest encountered. These forms are very characteristic of *P. malariae* infections.

As a rule schizogony does not commence until the growing trophozoite almost fills the infected red corpuscle, though occasionally it may set in in a growing equatorial band form, which fills about half the red corpuscle. Schizonts were a prominent feature of the films taken on—

March 6th at 2 hours before the rigor.

March 12th at 5 hours before the rigor.

March 13th at 9 hours before the rigor.

March 22nd at 7 hours before the rigor.

March 25th at 9 hours before the rigor.

March 28th at 5½ hours before the rigor.

* Knowles and Senior-White. "Studies in the Parasitology of Malaria." (In Press.)

Mature rosettes, showing well differentiated merozoites, were only prominent in one film, the count on March 19th, half an hour prior to the rigor.

From these findings it is possible to work out a rough "time table" of the schizogony cycle of *P. malariae* as follows:—

Phase.	Duration in hours.		
Free merozoite	1
Ring phase	17
Growing trophozoite	47
Schizont	6
Mature rosette	1

With regard to mature rosettes, in which all the merozoites had become clearly differentiated, but where rupture of the rosette had not yet taken place, we encountered in all 70 of these forms—most of them in the films taken on March 19th. Their distribution with regard to the number of merozoites present was as follows:—

6 merozoites were present in each of 3 rosettes.

7 merozoites were present in each of 13 rosettes.

8 merozoites were present in each of 29 rosettes.

9 merozoites were present in each of 21 rosettes.

10 merozoites were present each in 4 rosettes.

Thus the number of merozoites produced by *P. malariae* is very constant and shows but little variation. The mean of the above figures works out at 8.1.

Owing to the extremely heavy character of the infection in this patient, we had the opportunity of seeing certain appearances that we had never previously seen in infections with *P. malariae*. Thus accolé rings were not uncommon—a finding which never occurs in light infections with this species. Also dual infection of the same erythrocyte was seen three times, the findings being—

Ring plus ring once.

Trophozoite plus trophozoite once.

Macrogametocyte plus macrogametocyte once.

We had never previously seen dual infection of the erythrocyte in infections with *P. malariae*.

5. *Gametocytes*.—Gametocytes were encountered in 20 out of the 27 counts carried out; and constituted 184 out of 2,984 parasites met with, or 6.2 per cent. Males were to females as 82:102 or 1:1.2. (For the definition of what we believe to be the male and female gametocytes of *P. malariae* we may refer the reader to Knowles' *Introduction to Medical Protozoology*, 1928, pp. 391, 392.) Females outnumbered males on 8 occasions; males outnumbered females on 6 occasions; and on 6 occasions the numbers were equal.

On a study of Chart 2 it will be seen that there is a fairly close correlation between the

total parasite count and the gametocyte count, both tending to rise and fall together—though the gametocyte wave tends to follow the curve for total parasites some hours later. This would appear to indicate that the mature gametocytes are formed from some of the merozoites liberated at the previous schizogony cycle, but that they take a few more hours to mature than do the mature schizont rosettes. To some extent gametocyte production appears to fluctuate in a wave-like manner. Thus a first wave of production reached its peak on March 8th, and thereafter declined to zero on March 14th, although the total parasite count remained in the neighbourhood of 6,000 per c.mm. This was followed by a second wave which reached a peak on March 22nd, and thereafter declined, although the total parasite count remained in the neighbourhood of 8,000 to 10,000 per c.mm. Gametocytes disappeared very rapidly after quinine administration, and these forms appear to be equally susceptible to destruction by quinine as do the asexual forms.

One interesting point remains to be recorded, however. In the blood films taken on March 4th, before the counts were commenced, and two days before the patient's first rigor, scanty gametocytes were present. These could hardly have been derived from pre-gametocyte forms injected with the donor's blood on the 17th February, for the whole of the evidence in Table 1 and Chart 2 goes to show that the gametocytes are relatively short-lived forms. Thus it will be seen that a gametocyte count of 1,800 per c.mm. on March 8th fell to zero by March 14th, and one of 2,400 on March 22nd fell to 280 per c.mm. within 24 hours. We doubt whether the duration of life of a mature gametocyte of *P. malariae*, which is not ingested by an anopheline mosquito, and continues to be present in the circulating blood, exceeds six days. It seems reasonably certain that the gametocytes seen on March 4th were derived from merozoites liberated into the patient's plasma at the previous schizogony cycle, at a time when the infection was still at a sub-febrile level. In this case it has to be realised that gametocytes may appear at the earliest phases of an infection with *P. malariae*. It will be seen that gametocytes were still present in the blood of the second patient whose case is quoted in this paper, after a chronic infection with *P. malariae* of more than five months' duration. Gametocyte production therefore appears to be continuous throughout the whole course of an infection with *P. malariae*.

6. *Quinine*.—The Bass culture of April 9th was negative. This was after the administration of 200 grains of quinine sulphate in solution in ten days. No shorter course of quinine therapy (without alkalies) would seem to be efficacious in sterilizing the patient of his parasites.

Conclusions.

1. Quartan malaria may be a very severe disease, associated with very high parasite counts. On the other hand in chronic and relapsing cases of long standing the counts are very low.

2. Even in a case of quartan malaria which is of progressive character, some 95 per cent. of the merozoites are destroyed at each schizogony cycle by the natural powers of resistance of the body. We believe that the mechanism of this destruction of parasites is by the production of lysins in the plasma (possibly assisted by phagocytosis of merozoites by the endothelial cells of the internal viscera).

3. In primary quartan malaria the fever of invasion tends to be somewhat irregular; it is only as the infection becomes well established that typical quartan periodicity is attained.

4. In the schizogony cycle of *P. malaria* the free merozoite stage only lasts about 1 hour; the ring stage some 17 hours; the growing trophozoite stage 47 hours; the stage of schizogony some 6 hours; and the mature rosette stage about 1 hour. The number of merozoites produced is very constant; about 8 in the majority of rosettes.

5. In heavy infections with *P. malaria* accolé rings are encountered, and also double infection of the same erythrocyte with two parasites.

6. Gametocytes constitute some 6.2 per cent. of the total parasite population of *P. malaria*. The curve of gametocyte production appears to follow that of the schizogony cycle, but at a period some hours later. The gametocytes do not have a life of much more than six days. They are rapidly destroyed by quinine treatment. Gametocytes may appear in an infection with *P. malaria* at the very commencement of the fever.

7. A course of 200 grains of quinine sulphate (without alkalis) in ten days appeared to have completely eradicated the infection.

ENTEROCOCCUS BACTERIEMIA IN ASSOCIATION WITH INFECTIONS WITH *BACILLUS TYPHOSUS*.

By G. SHANKS, B.A., M.D., C.M.,

MAJOR, I.M.S.,

Professor of Pathology, Medical College, Calcutta,

G. P. KHAN, M.B.,

Formerly Clinical Pathologist, Medical College Hospital, and

B. P. TRIBEDI, M.B.,

Clinical Pathologist, Medical College Hospital.

(From the Department of Pathology, Medical College, Calcutta.)

At the outset we wish to state that the organisms to which we refer as enterococci are those conforming to the description given by Besson(1), who states that "the enterococcus of Thiercelin(2) is a saprophytic microbe susceptible of becoming pathogenic; it is encountered in man in the gastro-intestinal tract and elsewhere. Becoming virulent it may cause affections of the digestive tube, and is capable of invading the organism and of determining septicæmias and localising in other situations."

When beginning the observations here recorded we were employing the term "*Streptococcus faecalis*," having adopted Holman's(3) classification of the group. As our studies progressed, for reasons which we shall record in a later paper, when we consider in detail the characters of the organisms observed, and in order that confusion with the more typical streptococci might not occur, we adopted the name enterococcus, having concluded with Dible(4),

and Besson, that this term might be reserved for them and that its use was justifiable.

During the past few years our attention at the Medical College has been directed to the study of the faecal flora and especially to the "stool cocci."

In connection with these investigations we have been interested in a series of cases of fever, most of them due to infection with *B. typhosus*, in which we have secured the enterococcus in cultures of the blood, either coincidentally with the former organism, or alone.

We have gone through most of the literature available locally without having encountered any descriptions of similar findings, although numerous cases have been recorded, singly or in series, in which enterococcus bacteriæmia has been observed, of which the following are examples:—

(a) Andrewes and Horder(5) in their articles mention recovering it in four cases of septiciæmia: two of meningitis, once in association with a parametritic abscess, and once with acute otitis media, and also in four cases of malignant endocarditis.

(b) In French literature as cited by Besson(1) there have been recorded cases of infectious endocarditis, due to the enterococcus,

and he further states that this micro-organism may give rise to septiciæmia, either secondary to another infection, or primarily.

(c) Among such cases may be mentioned that reported by Rouslaacroix, Zuccoli and P. Martin(6) in which the enterococcus was secured in a case of malignant endocarditis with septiciæmia. As a matter of fact the French group the various manifestations of pathogenicity on the part of the enterococcus under the heading "enterococcie."

(d) During the war Houston and McCloy(7) secured the enterococcus in blood cultures from a number of cases which they classified on clinical grounds into three divisions:—(a) septiciæmia, (b) 'trench fever,' and (c) myalgia groups. Their cases in general had relatively mild febrile courses, no fatal results were recorded, and none were associated with enteric infections.

(e) Donaldson(8) refers to the recovery of the enterococcus from the uterus in a single case of puerperal septiciæmia.

During the past five years we have secured the enterococcus in blood cultures from several patients in the wards of the Medical College Hospital. The chief features of this series of cases are indicated in Table I.

TABLE I.

No.	Patient.	Day of disease or dates.	Result of culture of blood.	Result of agglutination reaction.	REMARKS.
1	Indian male. Age 7.	28th day of disease.	<i>B. typhosus</i> and enterococcus together.	Positive with <i>B. typhosus</i> to 1 in 250, end point not observed.	Continued fever of enteric type. Patient recovered.
2	Indian male ..	15th day of disease.	Sterile	Positive with <i>B. typhosus</i> to 1 in 83.	Temperature Chart 1.
		30th day of disease.	Enterococcus alone ..	Positive with <i>B. typhosus</i> to 1 in 500.	Continued fever of enteric type. Patient recovered.
3	European female. Age 12.	27-8-24 ..	Sterile	Positive with <i>B. typhosus</i> to 1 in 70.	
		9-9-24 ..	<i>B. typhosus</i>	
		17-9-24	Pus in urine, culture gave <i>B. coli</i> .
4	Indian child ..	2-10-24 ..	Enterococcus alone	Patient died.
		Enterococcus alone ..	Positive with <i>B. typhosus</i> to 1 in 250.	
		Fæces culture, <i>B. typhosus</i> present.
5	European female adult.	Enterococcus alone ..	Positive with <i>B. typhosus</i> to 1 in 83.	
6	European child	Enterococcus alone ..	Positive with <i>B. typhosus</i> to 1 in 83.	
7	European male adult.	<i>B. typhosus</i> and enterococcus together.	Positive with <i>B. typhosus</i> to 1 in 250.	
8	European male adult.	15-6-25 ..	Enterococcus alone ..	Negative with organisms of the typhoid, paratyphoid group.	
9	Indian male adult.	22-6-25 ..	Enterococcus alone	Positive with <i>B. typhosus</i> to 1 in 250.	
10	Indian male adult.	9-7-25 ..	Enterococcus alone ..	Positive with <i>B. typhosus</i> to 1 in 250.	Urine on culture gave a growth of <i>B. typhosus</i> and enterococcus.

TABLE I—*contd.*

No.	Patient.	Day of disease or dates.	Result of culture of blood.	Result of agglutination reaction.	REMARKS.
11	European female. Age 8.	12-4-27 ..	Enterococcus alone ..	Negative with organisms of the typhoid, paratyphoid group.	Ten days' fever before admission. Temperature normal from 12th day of disease. Five days in hospital. Urine on culture, gave a growth of <i>B. typhosus</i> and <i>B. coli</i> .
12	European female.	11th day of disease.	Sterile	Positive with <i>B. typhosus</i> to 1 in 500.	
		21th day of disease.	<i>B. typhosus</i> and enterococcus together.	Positive with <i>B. typhosus</i> to 1 in 500.	Second culture of blood made during relapse of five days' duration.
13	Indian male. Age 10.	22-5-28. 11th day of disease.	Contaminated ..	Positive with <i>B. typhosus</i> to 1 in 500.	Approximately the 11th day of disease in a typical attack of typhoid fever clinically.
		18th day of disease.	Enterococcus ..	Positive with <i>B. typhosus</i> to 1 in 2,500.	
		21st day of disease.	Positive with <i>B. typhosus</i> to 1 in 2,500.	No complications. Patient recovered.
14	European female adult. Age 36.	19th day of disease.	<i>B. typhosus</i> alone ..	Negative with organisms of the typhoid, paratyphoid group.	Temperature Chart 2.
		23rd day of disease.	Enterococcus alone	Second blood culture made during "relapse" or exacerbation.
		26th day of disease.	Positive with <i>B. typhosus</i> to 1 in 500.	Patient recovered.
15	Indian male adult. Age 20.	14th day of disease.	<i>B. typhosus</i> and enterococcus together.	Result unsatisfactory on account of hæmolysis of blood.	
		19th day of disease.	Positive with <i>B. typhosus</i> to 1 in 500.	Typical attack clinically with remittent temperature ranging from 101° to 103.5°F.
16	European female adult.	14th day of disease.	Enterococcus alone ...	Positive with <i>B. typhosus</i> to 1 in 50.	Leucocyte count 19,500 per c.mm. (82% neutrophils). Faeces, showing mucus and cells on culture gave <i>B. typhosus</i> with enterococcus of which the latter constituted 70% of the colonies.
		31st day of disease.	Leucocyte count 19,000 per c.mm. (80% neutrophils). Fever continued for 48 days.
17	Indian male ..	14th day of disease.	<i>B. typhosus</i> and enterococcus together.	Positive with <i>B. typhosus</i> to 1 in 83.	Clinically a typical typhoid infection.
18	Male, aged 18 ..	18th day of disease.	Positive with <i>B. typhosus</i> to 1 in 250.	Date 1-1-30. No. 227-30.
		49th day of disease.	Culture of faeces gives <i>B. typhosus</i> . 31-1-30. No. 327-30 with 80% of colonies enterococci.
		54th day of disease.	<i>B. typhosus</i> and enterococcus together.	5-2-30. No. 402-30.
		61st day of disease.	Culture of urine gives <i>B. typhosus</i> . 12-2-30. No. 481-30.
		66th day of disease.	<i>B. typhosus</i>	Fever continuous throughout without any intermissions.

TEMPERATURE CHART 1.

1 = First examination of blood. 2 = Second examination of blood.

TEMPERATURE CHART 2.

1 = First examination of blood. 2 = Second examination of blood. 3 = Third examination of blood.

TABLE I—concl'd.

No.	Patient.	Day of disease or dates.	Result of culture of blood.	Result of agglutination reaction.	REMARKS.
19	European male. Age 19.	Admitted 27-3-30. 29-3-30 (10th day of disease). 31-3-30 (12th day of disease). 2-4-30 (14th day of disease). 13-4-30 (25th day of disease). 25-4-30 (37th day of disease). 9-5-30 (48th day of disease). Enterococcus alone	Negative with organisms of the typhoid and paratyphoid group. Negative with organisms of the typhoid and paratyphoid group. Positive with <i>B. typhosus</i> to 1 in 83. Positive with <i>B. typhosus</i> to 1 in 125.	<i>B. typhosus</i> in culture of faeces. The temperature was at a level about normal from the 25th day of disease until the 35th, when an exacerbation to 103° occurred lasting three days. Clinically a typical typhoid infection.

As far as the characters of these organisms are concerned, they have generally, when first isolated, shown short chain formation—four to eight elements in line—and, on subculture, diplococcal forms.

None have been hæmolytic, but most have produced a slight green or greyish green tint on blood agar.

The earlier strains secured from the blood gave acid reactions when grown in lactose, mannite, and salicin (Holman)—Table II.

As our studies have progressed, we have been using more elaborate methods of identification as indicated by Schönfeld (9), Meyer and v. Schönfeld (10), Meyer (11), and Weatherall and Dible (12)—Table III.

TABLE II.

Case No.	Morphology.	Blood-agar.	Broth.	Lactose.	Mannite.	Salicin.
1	Short chains and diplococci.	Greenish gray	Uniformly turbid.	+	+	+
2	Do.	+	+	+

11	Do.	+	+	+

TABLE III.

Case No.	Morphology.	Blood-agar.	Broth.	Lactose.	Mannite.	Salicin.	Aeskulin.	Raffinose.	Thermo-resistance.
12	Diplococci few short chains some show capsules.	Grayish green.	Uniformly turbid.	+	+	+	+	—	Not estimated.
13	Diplococci lance shaped some showing capsules.	Grayish. No hæmolysis.	Do.	+	+	+	+	—	Do.
14	Diplococci lance shaped.	No greening.	Do.	+	+	+	+	—	+
15	Do.	Distinct greening.	Do.	+	+	+	+	+	+
16	Diplococci few short chains.	Grayish green.	Do.	+	+	+	Not set up.	Not set up.	Not estimated.

TABLE III—concl'd.

Case No.	Morphology.	Broth.	Lactose.	Mannite.	Salicin.	Aeskulin.	Raffinose.	Thermo-resistance.	Inulin.
17	Lance shaped diplococci.	Uniformly turbid.	+	+	+	+	—	+	Not set up.
18	Diplococci ovoid coarse.	Do.	+	+	+	+	Not set up.	+	+
19	Lance shaped diplococci.	Do.	+	+	+	+	Do.	+	+

+ = acid.

Thermo-resistance + = 30 minutes at 60°C.

An analysis of these characters is being carried on by us at present in connection with our investigations of the occurrence and nature of faecal cocci in cases of dysentery and colitis.

In connection with the cases of which the features are outlined in Table I, the chief observation is that, in the majority of them the enterococcus was obtained in culture of the blood during the course of an infection with the typhoid bacillus.

Case No. 8 is an exception in that no bacteriological evidence was secured indicating enteric fever.

The laboratory evidence in three cases, Nos. 5, 6 and 9, rests on the agglutination reaction alone. Clinically, however, these were of the enteric type.

The only fatal termination occurred in Case No. 3, to which various factors, other than the enterococcus, would seem to have contributed.

In all cases the finding of the enterococcus in cultures of the blood in the later stages of the disease, was obtained during slight febrile exacerbations.

Summary.

A series of observations are recorded in which an enterococcus bacteremia occurred as a complication of typhoid fever.

From these observations it seems justifiable to conclude that the enterococcus was a temporary, and relatively innocuous, invader of the blood stream.

We have not observed in any case the occurrence of a true streptococcus septicaemia associated with a typhoid infection.

INFECTION BY A GNATHOSTOME SIMULATING MASTOIDITIS.

By SUBODH DATTA, M.B. (Cal.), L.M., F.R.C.S. (Edin.).
(From the Department of Surgery, Carmichael Medical College, Calcutta.)

The patient, a Hindu female, *æt.* twenty years, of Howrah, who had never been out of Bengal, was admitted to hospital on the 5th August 1929.

Previous history.—About two months before the above date the patient had a sore throat followed by a pain in the right ear. The next day there was a discharge of blood from the ear and the pain subsided. During treatment before coming to hospital three thread-like structures came away from the right ear. They were not specially examined, but were identified by naked eye examination as possibly blood clots.

On admission.—The patient complained of severe earache, and she had a discharge of blood from the right ear, which had been present for the past fifteen days. A swelling appeared two days before coming to hospital, which at first involved the right mastoid, temporal, and preauricular regions, it had now spread until both eyelids of the right eye were involved. There was no impairment of hearing, and the ear drum was intact, but congested.

Blood examination revealed nothing characteristic, the count was as follows:—

Hæmoglobin	42%
R.B.C.	2,100,000
W.B.C.	6,250
Polymorphs.	55%
Small Lymph.	30%
Large Lymph.	10%
Eosinophil.	5%

A provisional diagnosis of mastoiditis was made, and three days after admission the

swelling had considerably subsided. Under chloroform anæsthesia the usual mastoid incision was made, and on exposing the bone a small worm-like body was seen at the upper end of the incision on the deep surface of the temporal muscle. This was removed and it was found to be a living worm. Mastoidectomy was not carried out as the bone appeared healthy. Ten days after the operation the patient was discharged with no further symptoms and with the wound almost healed. Up to the time of writing this note, nearly six months after the operation, the patient has been quite free from any ear symptoms, or other evidence of disease in the region previously affected.

My thanks are due to Dr. Mrigendralal Mitra for permission to operate on the case and to publish this note.

THE PARASITE.

By P. A. MAPLESTONE, D.S.O., M.B., CH.B., D.T.M.

(From the Hookworm Research Laboratory, Calcutta School of Tropical Medicine and Hygiene.)

THE worm removed from the above case was handed to me for identification.

It is a typical male *Gnathostome*. The length is 15.1 mm. and the maximum diameter, which is a little behind the middle of its length, is 1.4 mm. The diameter of the head bulb is 0.574 mm. and its length is 0.257 mm. There are eight rows of single pointed spines on the head bulb, quite typical in their appearance. The body is covered anteriorly with the usual broad spines with three to five points, these give place to finer single pointed spines which finally disappear at a distance of 6.5 mm. from the anterior end. The four cervical sacs end 1.68 to 1.98 mm. from the anterior end, and the œsophagus is 3.6 mm. in length. The posterior extremity is furnished with four large papillæ on each side and its ventral surface is covered with fine closely set spines. The spicules are 1.16 and 0.6 mm. in length respectively.

There is little doubt that this parasite is a specimen of *Gnathostoma spinigerum* Owen, 1836 [or preferably *G. robustum* (Diesing, 1838)]. It is similar to *G. spinigerum* (Leiper, 1911) and *G. spinigerum* (Levensen, 1889), but comparison of the dimensions given by Levensen and Leiper with those of the present specimen indicate that it is more mature than either of the above worms. Indeed the measurements given for the adult male of *G. spinigerum* are in some instances smaller than those in the present example, it is therefore probable that this worm is fully grown.

Discussion.—This case is of interest for two reasons. In the first place human infection by *Gnathostoma* was not known to occur in India before the record of a case by the writer only last November, and the second point of interest is that the effects produced by this worm

suggested such a serious condition as mastoiditis.

The history and bibliography of human infection with *Gnathostomes* has been given so recently by the writer (*Indian Medical Gazette*, November 1929, Vol. 64, p. 274) that it is not proposed to repeat it here, and the reader is referred to the above article.

This case makes the twelfth on record, and it is interesting to note that of the four cases in which the sex has been determined they have all been males. Another interesting fact is that the worms have been found in various stages of development, from quite immature larvæ up to the specimen in the present instance, which is apparently a fully grown worm. This raises the question as to whether these worms are capable of entering the body at different stages of their life history, or whether, having gained entrance to the human host as larvæ, they are able to undergo development to apparent maturity in the tissues.

ON THE RELATIVE FREQUENCY OF SUPRACLAVICULAR AND INFRACLAVICULAR PULMONARY TUBERCULOSIS, AND ITS BEARING ON THE PROGNOSIS OF THE DISEASE IN INDIA.*

By M. KESAVA PAI, M.D.,

and

K. VASUDEVA RAO, M.D.

(From the Tuberculosis Hospital, Madras.)

IN the diagnosis of early pulmonary tuberculosis by physical signs, it has been taken as a clinical dogma that signs observed at the apex, i.e., in the first intercostal space and above should, as a rule, be considered to be due to tuberculous disease, whilst signs lower down with nothing abnormal above the second rib in front should be looked upon as non-tuberculous in nature.

With the introduction of the Roentgen rays and their application to the diagnosis of pulmonary tuberculosis, our ideas of the pathology of tuberculosis of the lungs have undergone a considerable change. The comparative freedom from opacity of the hilum of the lung in the infant, the increase in the area and depth of this opacity in the growing child and adult, the frequent presence of opaque calcareous masses in the region of the hilum and the adjoining lung substance, the post-mortem findings of healing and healed lesions, especially at the root of the lungs and in the mediastinal glands of clinically non-tuberculous individuals dying from other causes, and the observations made in all modern countries on the incidence of allergy increasing rapidly from infancy to adult life in apparently normal individuals, as indicated by the cutaneous reaction of Von

* Being a paper read at the Medical and Veterinary Research Section of the Indian Science Congress, Allahabad, January 1930.

Pirquet, have gradually led the pathologist to a change in his views as regards the origin and course of the disease in the lungs.

It is a common observation made by the roentgenologist and the pathologist, that there is a large number of cases where signs of tuberculous deposit are evident in the region of the hilum glands and the lung substance surrounding it, without any signs of implication of the apex, and a close study of serial roentgenograms of a large number of cases of early and suspected pulmonary tuberculosis has revealed the presence of tuberculous extensions from the region of the hilum into the periphery of the lung more frequently in an upward and outward direction than towards the base, without any involvement of the actual apex. This has been explained to be due to extension of infection along the lymphatic channels connecting the central lymphatic glands in the mediastinum with the lymphoid tissue in the periphery of the lung, the anastomotic channels between the mediastinal glands, the lymphoid tissue at the apex, and the supraclavicular lymphatics being considered to be the most patent and free of all, causing a predominance in the extensions towards the apex.

In the pre-Roentgen days when the localization of tuberculous disease in the lungs had to be made by physical examination alone, which could not as a rule reveal disease at the hilum, the first signs were, for obvious reasons, noticed mostly at the apex, but with the introduction of X-ray diagnosis and the confirmation of physical diagnosis with the skiagram, it has become increasingly evident that a large number of active cases of pulmonary tuberculosis show the initial lesion below the apex, which remains free up to a comparatively late stage of the disease. Thus Fishberg(1) at the last annual meeting of the British Medical Association at Manchester laid great emphasis on what he called the subapical or subclavicular localization of tuberculous lesions in the lungs, predominating over the true apical.

William Ewart(2) and Kingston Fowler(3) in England, Fishberg and others in America, and a number of pathological anatomists on the continent have similarly described that the early lesions, as well as the cavities resulting from their break-down, are much more frequent at a distance lower down in the first and second intercostal spaces than at the apex, and Fishberg(1), by a study of the clinical history of a large number of such cases, considered that the subclavicular type of case was more acute and more virulent than the true apical cases.

The diagnosis of apical tuberculosis by physical examination alone without confirmation by the X-rays is by no means free from error. A comparative study of a larger number of cases by physical signs and by roentgenology has made it sufficiently evident that the presence of such physical signs as harsh breath

sounds, broncho-vesicular breath sounds, and even occasionally bronchial murmurs at the apex is not at all inconsistent with an apex free from disease, the causation of such abnormal breath sounds being apparently due to hilum disease or to density of tissue by deposit, fibrosis, etc., in the upper lobe between the root of the lung and the apex. It is thus evident that the diagnosis of the pathological condition by physical examination alone cannot be considered to be accurate or reliable.

In the investigation which forms the subject of this paper we have therefore relied more upon the X-ray appearances of the lungs than on the results of physical examination. It must however be mentioned that with the exception of a comparatively small proportion of cases the results of physical examination have closely agreed with the X-ray findings.

The cases constituting our series can, for purposes of pathological classification, be divided into six groups:

1. Cases of extensive implication of the lungs, including the apex, in which it was not possible to locate the original focus with certainty.
2. Cases where the lesion could be localized in the infraclavicular region, i.e., in the first or second intercostal spaces.
3. Cases in which the lesion was in the middle zone of the lung, with the rest of the lung parenchyma in a healthy condition.
3. Cases in which the lower zone of the lung was the seat of tuberculous disease, with no implication of the upper two-thirds.
5. The true apical cases where the focus was at the actual apex alone, i.e., in the supraclavicular region.
6. Cases where there was evidence of implication of the hilum glands, with little or no signs of disease in the parenchyma of the lung.

A large number of the cases, viz., 240 out of 1,497, belonged to class I, evidently on account of the cases not coming for admission into hospital until they reached an advanced stage. In a large number of cases, however, it was possible, by a close scrutiny of the skiagrams to arrive at a decision as to the primary seat of the disease. Thus cases showing extensive fibrosis or a fibro-calcous involvement in the infraclavicular region, with recent infiltration and soft deposit at the apex and downwards towards the mid zone and base, could with justification, be classified as cases where the primary focus was subapical. Many of these cases showed a cavity in the first or second intercostal space, with thick fibrosed walls and situated more towards the outer aspect of the chest. Some others of this group showed very extensive and dense involvement of one lung, with a commencing focus in the subclavicular

region of the collateral lung, with the apex of the latter quite free from disease.

A very common seat of deposit in the second and third groups was the axillary aspect of the second or third intercostal space, with the rest of the parenchyma intact. Cases with fairly extensive involvement of the middle zone and a cavity in it outside the hilum were also common in the third group.

Twenty cases had involvement of the lower zone alone, with cavities in 4 cases.

The true apical cases were very few, there having been only 4 in the series.

The most common type of the incipient cases that came under treatment were the "hilum" cases, of which there were 457 in the series. These patients were admitted into the hospital for low and irregular pyrexia, bronchitis and general symptoms including loss of appetite and fatigue on exertion, with no definite signs

general condition indicates marked toxæmia, the consequent delay in the diagnosis by the majority of medical men who have no X-ray facilities at hand, and the neglect of early treatment, account in part for the worse prognosis of pulmonary tuberculosis in this country. *The duration of the disease*, as judged by the history of the cases, seems to indicate the more frequent occurrence of the acuter cases here than in Europe. Cavities have been seen in many cases that have given a history of four weeks or less since the onset of the first symptoms, and an occasional case has come into the hospital for a hæmoptysis with practically no history of previous cough, in which a skiagram has shown definite signs of a small cavity at or near the hilum or in the upper lobe.

Table I gives an idea of the incidence and the prognosis in the three stages of pulmonary

TABLE I.
Comparative results of treatment in different stages in England and in Southern India:

	RESULTS IN ENGLAND.			RESULTS IN MADRAS.		
	Arrested and much improved.	Relieved.	No benefit.	Arrested and much improved.	Relieved.	No benefit.
I. Stage	90%	9%	1%	60%	34%	6%
II. Stage	81%	17%	2%	69%	18%	13%
III. Stage	45%	37%	18%	32%	34%	34%

of pulmonary tuberculosis, excepting harsh breathing at the apices or in the hilum region, or broncho-vesicular breath sounds in those areas, deficient entry of air into the apices or bases or both, and slight impairment of the percussion note over these regions. Tubercle bacilli could not as a rule be detected in the sputum of these cases. Von Pirquet's reaction gave a positive result. Skiagrams showed marked opacities at the hilum of the lungs, often with calcified deposits in and about them, peri-bronchial thickening with heavy bronchial shadows especially towards the bases, and what looked like calcified spots in the course of the linear bronchial shadows giving them an irregular beaded appearance. A certain amount of general fibrosis, marked in a few cases, as a rule, was present. No signs of soft deposit in the pulmonary parenchyma were evident.

Judging from the above figures there seems to be a marked difference in the ratio of supra-clavicular to infraclavicular lesions found in Southern India, viz., about 1 per cent. compared with those found in western countries, where they seem to constitute about 15 to 20 per cent. of all early cases.

The difficulty of locating early infraclavicular lesions by physical examination, even when the

tuberculosis in the Madras Tuberculosis Hospital, compared with the corresponding figures for England as given by Kingston Fowler(4). The difference between the Indian and English figures is very striking.

1. Whilst these are 15 to 20 per cent. of supraclavicular amongst early cases in western countries, there are much fewer of such cases in Southern India (about 1 per cent. in our series).

2. The acuteness of type and the prognosis of pulmonary tuberculosis for all ages are more unfavourable in this country than in Europe. This is indicated in Table I where it is seen that whilst 99 per cent., 98 per cent., and 82 per cent. of the cases benefit in the I, II and III stages respectively in England, the figures of the Madras Tuberculosis Hospital show a similar improvement in 93 per cent., 87 per cent., and 66 per cent. respectively. In the same table it is also seen that the figures for cases arrested and much improved are 90 per cent., 81 per cent., and 45 per cent. in England, but only 60 per cent., 69 per cent., and 32 per cent. in Madras. The fact that the Madras figure for improvement in stage II is better than that in stage I is apparently due to most of the stage II cases having been placed under artificial pneumothorax treatment.

Table II, which gives the relative incidence of primary localization, is very interesting.

TABLE II.
Analysis of 1,497 cases treated in the Madras Tuberculosis Hospital during 1926—1929.

Advanced cases	240
Subapical cases	389
Middle zone affections	145
Apical cases	4
Hilum cases	457
Basal affections	22
TOTAL			1,497

The hilum cases, where on account of the innate or acquired resistance of the individual infection has not proceeded beyond the hilum glands, naturally constitute the vast majority of the cases. This agrees with pathological findings which have revealed latent tuberculous lesions in lungs in 50 to 90 per cent. of persons dying from other diseases. The subapical cases stand next in frequency, and then come the advanced cases and the middle zone and basal affections. The true apical involvement is very rare, there having been only 4 cases in the series of 1,497.

Table III gives the prognosis of these different types. It is interesting to note that the

within a month of the onset of symptoms fare best, that patients with a history of 1 to 6 months are the most acute, and that cases giving a longer history than 6 months have a better prognosis, being more chronic in type. The majority of cases that came under observation were in the groups giving a history of 1 to 6 months of disease symptoms, which indicates that pulmonary tuberculosis of the more acute type predominates in this country.

It is not contended that the greater severity of the disease in India and the higher mortality amongst the tuberculous is due to a small degree of immunity, either racial, hereditary, or inherent in the country, where tuberculosis has been existent for centuries, and any racial immunity that can possibly result from generalized infection has had sufficient time to be established. It is presumably the social, economic and food factors, and possibly also the enervating climate that are responsible for the severer types of the affection and the higher mortality. Poverty, insanitation, ignorance, early marriage, and the tropical climate have each and all a part to play in this marked difference between the severity and prognosis of the disease in India and in the west; and the difference in the pathological localization in the lungs is most likely secondary.

TABLE III.
Results of treatment in the various types of pulmonary tuberculosis classified according to localization.
Madras Tuberculosis Hospital.

	Arrested.		Relieved.		No result.		Total number.
Subapical	64	40.4%	54	34.1%	40	25.4%	158
Hilum	103	60.9%	54	31.9%	12	7.2%	169
Middle zone	36	45.5%	24	30.3%	19	24.2%	79
Advanced	15	25.0%	21	35.0%	24	40.0%	60
Basal	4	18.2%	7	31.8%	11	50.0%	22

advanced and basal affections give the worst results, the middle zone and subapical affections stand next, and the hilum involvements are the most favourable.

Table IV gives an idea of the prognosis according to the duration of the disease. It is very interesting to note that patients coming

ON A SIMPLE SOLIDIFIED HÆMOGLOBINISED SALINE AGAR MEDIUM SUITABLE FOR SURFACE CULTURES OF LEISHMANIA AND ALLIED FLAGELLATES.

By R. ROW, O.B.E., M.D. (Lond.), D.Sc. (Lond.).

Professor of Pathology, Grant Medical College.

(From the Pathology School, Grant Medical College, Bombay.)

IN another communication⁽¹⁾ published in 1912, the author of this memoir has described the value of a simple hæmoglobinised saline solution as a medium suitable for culturing *Leishmania* and allied protozoa, and this has been the medium of choice in his hands and subcultures have been successfully kept up from month to month with ease, from the original virus isolated from human cases 18 years ago, as the fluid does not appreciably alter in composition or density and the flagellates are found active even after six weeks. But, there are one or two drawbacks in dealing with cultures in a fluid medium and these are (1) the difficulty of obtaining large quantity of the flagellates, when required for special purposes, and (2) the manipulations required for washing these free from the liquid in which they flourish are far too complex and laborious when one has to deal with them or their products in bulk and purity. These difficulties are best met by having surface growths on solidified media to allow of their being scraped off the surface as in bacterial cultures. Nicolle and Manceau had described the possibility of obtaining growths in solid media in 1911, and later,⁽³⁾ the author of this paper had also referred to the nature of these growths in the form of a film in the dry part of the NNN medium, above the water line of the condensation fluid. In describing the different stages of the morphology of these parasites in their reversion from the flagellates to the body forms, it is regrettable that no further efforts were made in this direction until recently. To J. C. Ray belongs the credit of re-awakening one's interest in studying these cultures in solidified media by the demonstration⁽²⁾ of his results at the meeting of the Royal Society of Tropical Medicine and Hygiene (London) in June 1929. In this demonstration Ray used for his solid medium Noller's formula, consisting of equal parts of a glucose peptone agar and defibrinated rabbit's blood, which is added to the agar at 55°C. while it is still liquid, and therefore it is almost identical with that originally recommended by Novy and MacNeal, and cultures are made by planting the infecting material on the surface of this nutrient blood agar mixture in Petri dishes. But unfortunately this technique of plating often proves unsatisfactory for maintaining the cultures free from contamination, during the long time of at least two weeks required for obtaining a fair quantity of the culture, and this is

why the author of this memoir has ventured to submit the result of this investigation regarding the technique and composition of his culture medium, bearing in mind the virtues claimed by him for the simple hæmoglobinised saline solution going by his name. These qualities are the simplicity of the composition, the ease and expedition of manufacture and the economy in the use of rabbit's blood available, and the simplicity of the technique to afford the optimum conditions for the cultures to thrive in and survive without contamination for several weeks, and thus minimize the labour and trouble of sub-culturing at frequent intervals. The composition of the medium is the same as that of the hæmoglobinised saline solution but with the addition of a suitable quantity of agar necessary to yield a satisfactory slope in test tubes, when the mixture is allowed to set.

Technique.—For this purpose an ordinary three per cent. agar medium is made in normal saline, and of this 6 c.c. each are distributed into wide test tubes (one inch diameter), sterilized and stocked. When required the agar is melted and an equal quantity of the hæmoglobinised saline is added to each tube at 55°C. when the agar is still liquid, and the tubes are sloped and the mass allowed to set. The simple agar basis may be replaced by nutrient peptone agar with or without the addition of glucose, and the NaCl of the simple normal saline by Ringer's fluid, and although these modifications may have each its own advantage, the main part of the technique is (1) the use of wide test tubes to do away with the plating in Petri dishes, and (2) the addition of hæmoglobin solution instead of defibrinated blood for economy (as 6 c.c. of this can easily give 16 culture tubes). For after all it is the saline hæmoglobin, even in dilution, which is the nutrient for the parasites' growth.

There are one or two technical details which, being found important by experiment, may be mentioned in this connection.

1. It is essential to have a dry surface, i.e., free from drops of condensation fluid, at the site of inoculation. This is secured by allowing the slopes to remain undisturbed overnight and then letting the condensation fluid collect at the bottom of the slopes by having them upright first at 37°C. for some hours, and then in the ice box, and when all the condensation fluid has drained to the bottom, to suck this up with a pipette and let the slopes rest for some hours with the flat surface uppermost. Then inoculate the surface carefully, with a drop or two of the infecting material (which may be either from an active culture in the NNN or Row's medium, or from an emulsion in normal saline of a loopful of a suitable surface growth) taking the precaution to confine the limits of the inoculated area well within the borders of the dry surface and from the bottom, and leave the infected tube in the

slanting position for some minutes with the planted patch uppermost, until the infecting material has practically dried on the agar surface, *vide* Fig. 1.

FIG. 1.

FIG. 2.

FIG. 3

Solidified hæmoglobin agar.

Water of condensation

Patch of infected area.

2. Add carefully one or two c.c. of this sucked up condensation fluid or normal saline to the infected tube without wetting or touching the infected part of the slope, and incubate the inoculated tube at 20 to 22°C. placed with the planted surface downward. This is important if one wishes to have a rich flagellate mass, because the inoculated flagellates will grow best in surface culture, when they are in an atmosphere saturated with moisture, and this is provided for by the condensation fluid lying in a layer at the bottom along the side of the tube so placed and at the same time separated from the inoculated surface, *vide* Fig. 2.

If these details are not attended to and if the slopes are allowed to be in the cold incubator without the addition of the normal saline and with the planted surface uppermost, *vide* Fig. 3, the agar medium tends to dry up and the oxy-hæmoglobin saline gets both concentrated and altered into met-hæmoglobin by age and desiccation and, instead of having a flagellate culture, one gets a reversion to the O body stage as described elsewhere(3) by the author of this memoir.

3. These two positions of the infected tube in the incubator, and the presence or absence of an atmosphere saturated with moisture determine the morphological characters of the parasite, and have to be selected according to the particular phase of the parasite one chooses to experiment with.

4. The superiority of the surface growth on the solidified hæmoglobin agar medium, over the cultures in hæmoglobinised saline or NNN medium lies also in affording one the possibility of utilising a surface culture, even if contaminated in parts, for isolating the parasite in pure culture, and thus reducing one's considerable anxiety of sub-culture under these unforeseen accidents.

Characters of the Cultures.

The macroscopic appearances of a good culture are:—

1. A thin gummy film on the planted patch, transparent like the film of water on a glass surface, but tending to be slightly translucent with age and richness of the crop. Microscopically, there is nothing special to add to the previous observation, beyond the striking richness of the parasites even in the thinnest films.

ANGIOMA, TREATMENT BY DIATHERMY.*

By B. N. C. ROY, M.B.

Surgeon, Carmichael Medical College Hospital, Calcutta.

ANGIOMAS are tumours composed of channels filled with blood or lymph. Different names are given to them according to shape and size, or the nature of the material filling those channels.

Different authorities hold different views as regards their origin, their modes of growth, and their relation to the general systemic circulation. While treating cases of various types and in their various stages, by the diathermic method of treatment, particularly when, instead of completing the whole treatment in a few seconds time, one adopts the slow and persistent method, as I now prefer to do, under which very small fragments of coagulated tissues are gently scraped away, where we find different tissues composing the tumour responding differently to the effect of current and where we are inadvertently led to change the strength, type and the direction of current according as we approach the different depths and the different parts of the tumour; the view that appeals most to us is the one held by Ribbert, who tried to prove his point by injections. According to him angiomas take their origin from the embryonic anlagen which were destined to form circulatory vessels and which, for reasons unknown, could not take part in the formation of the general hæmolymph system. It is one of those types of tumours which Albercht defines as hamartomata.

True angiomas, then, are not mere dilatations of blood or lymph vessels of the general systemic hæmolymph system. They are not governed by the laws that govern the

* A paper read before the Clinical Meeting of the British Medical Association, Calcutta Branch, held on 14th February, 1930.

distribution of the systemic vessels. They, like all other neoplasms, are supplied with blood-vessels, but do not stand in intimate anastomotic relations with the adjacent circulation.

The blood-spaces forming the tumour are intimately mixed up with their nutrient vessels. The proportion of these two types of channels varies differently in different cases. On this fact depends the extent and character of hæmorrhage after injury or ulceration, the reducibility under pressure or the reduction in size after hæmorrhage, the presence of pulsation and so on.

The colour of the tumour varies according to whether the channels are filled with lymph or blood, whether there is a preponderance of capillaries or venules of the nutrient set, and whether pigments have accumulated in the supernatant skin—the amount and colour of such pigment. The final colour of the tumour, then, is the result of all these three factors working together in different proportions. The colour of the same tumour varies during the course of diathermic treatment, and that according as the treatment, in its successive stages, can produce an effect on these different factors. When diathermy acts more on the true channels of the tumour, either by coagulation, toning up the vessel wall or causing fibrous tissue formation around them, the tumour, if it be a hæmangioma, fast loses its bright-red or brick-red colour. On the other hand, when the diathermic heat and current influence more the nutrient set of vessels, a general loss of colour is noticed. And when diathermy facilitates the cutaneous circulation most, the pigments accumulated therein are quickly dispersed and the true colour of the neoplasm soon becomes evident. I have seen cases where the bluish colour of the skin totally misled me to think the tumour to be a lymphangioma, but as soon as the cutaneous pigments began to dwindle away the actual red colour of the hæmangioma became manifest and clear. The dispersion of cutaneous pigments overlying angiomas also takes place when, for some reason, the tumour is inflamed, as with increased circulation the phagocytic cells get a chance to carry away these pigments.

Angiomas are either congenital or acquired. The usual types are—hæmangioma, lymphangioma, capillary or simple and cavernous angiomas, border-line and mixed forms. Plexiform or cirroid angiomas of the scalp (tangled masses of pulsatile arteries). The lymphangomas are usually extensive and more diffuse than hæmangiomas,—macroglossia, elephantiasis, serotal tumours are the examples. Some of the cavernous or cystic types are called cystic hygromas, and others are endotheliomas.

The complications that may occur are:—

1. Circulatory disturbance.
2. Infection leading to inflammatory reaction in their substance. Lymphangiomas may

have periodical inflammatory reactions in this country, owing to filarial infection.

3. Ulceration and hæmorrhage.

4. Thrombosis with or without phlebitis, which may end in spontaneous healing.

The angioma may be a slightly raised but flat one, or a distinct fungating growth with or without a pedicle, or it may be wine-glass shaped—a growth with a base and a pedicle.

It may be situated in the skin of the face, scalp, groin, or any other part of the body. It may be in the muscle, as in the tongue, lips, intestines, urethra, and so on. It may also be in the internal viscera, such as the liver, cardiac valves, etc.

The cases that came under my treatment comprised a group of about forty, which practically covered the whole range of various types and stages of the growth. Those cases that are reported here while relatively few in number present different characteristics, and demonstrate the principal types of angiomas as well as the methods of application of diathermy suitable for each.

Case No. 1. Urethral Caruncle.—Mrs. J. G., Hindu female, aged 26 years. Operated on 18th April, 1929.

Since about a month previously she felt pain during micturition. She never suffered from urethritis or any other condition of the genito-urinary system to which this symptom could be ascribed. The pain during micturition gradually grew worse and in three or four days' time the patient felt some thickening about the urinary orifice. Both the pain and the thickening went on steadily increasing. There was no improvement under ordinary methods of treatment.

Under local anaesthesia the urethra was dilated, urethroscope examination made, and on puncturing the tumour nothing but blood came out. It was therefore diagnosed as a hæmangioma situated in the muscular coat of the urethra, covered with squamous epithelium. The pain was due partly to the pressure of the tumour on the nerves with which the part abounds, and partly to the obstruction and congestion consequent of the tumour growth.

It was a red sprouty swelling, affecting not only the posterior lip of the urethra, but had extended and involved the orifice all round. The constant strain during micturition, which was extremely painful, and the weight of the growth led to the prolapse of a portion of the urethra.

For want of a more appropriate name I call this tumour a urethral caruncle, which is believed to grow on the posterior lip of the female urethra. The tumour must have started somewhere on the external urinary meatus as a minute thing, but like all other fast-growing angiomas, which either from the beginning grow quickly or by trauma or some such stimulus stirring up dormant things to grow fast, it had extended and involved the urethra all round.

The pain was 50 per cent. less after the first application of diathermy. The tumour with all its symptoms disappeared after five applications. The urethra was slightly patulous for a fortnight more. The little fibrosis and thickening that appeared at the sight of the tumour, as a result of diathermic treatment, took about a month to disappear altogether. There is a danger of overdoing things in a case like this, as excessive treatment might lead to massive fibrous tissue formation and, the distribution being all round the orifice, this might lead to fibrous stricture of the urethra.

Case No. 2. Hæmangiomas on the groin and on the scrotum.—Mr. S. C. B., Hindu male, aged 34 years, saw me on the 26th May, 1929.

A red papule appeared on the right side of his scrotum, some four months previously. About a month

and a half after this, a similar one appeared on the groin. Both these went on growing till he came under diathermic treatment, as is shown in the illustration. The colour of these two tumours was different, the one on the groin was reddish, with an exceedingly thin supernatant skin, and composed of rapillaries, whereas

Case No. 2. Hemangiomas on the groin and on the scrotum, in a man aged 34 years.

the one on the scrotum was rather bluish—evidently composed of venules.

Altogether seven treatments were given to these, four to the groin one, as the skin was very thin and would not stand strong current, and three to that on the scrotum.

Case No. 3. Lymphangiomas on the right arm—R. G., a Christian female child, aged 5 years, was brought to me on the 12th October, 1929.

There were three patches of swelling—two on the forearm and one on the upper arm of the same side—on the right side. All of them were flat-topped, present from birth and considered to be birth-marks. They were more pigmented previously. Since about a year these patches became inflamed several times. During the inflammatory attacks the areas used to get swollen, thicker, more extensive, pinkish in colour (not bluish, its original colour) and painful, accompanied with a rise of temperature lasting for one, two or three days. All these signs of inflammation used to come on and disappear together, then everything came back to the status quo, except perhaps, what was lately noticed, that the areas were losing the extra pigments they had.

I gave her altogether seven applications of diathermy, every two or three days. The effect noticed after the first application was that one of them turned from blue to brown and dwindled in size. After the second application all the three patches became tougher and harder. During the course of the treatment, which took about a month, the usual periodical inflammation came on only once and then was of a very mild type. Since the treatment was completed, which is now about a year and a half, she has had no complaint. Now, there is practically no evidence of tumours except slight thickening of skin.

The points to be noted about this case were—although the tumours were bluish in colour they had nothing to do with the venous system, the colour was imparted to them by the hyperpigmentation of the superjacent skin. So, after inflammatory attacks, which increased the circulation of the parts, the phagocytic

cells had opportunities to carry away the pigments with consequent reduction in the depth of bluishness. The effect of diathermic treatment was first, as in all other inflammatory conditions, to reduce the inflammation and its occurrence, and secondly, not to coagulate the contained lymph, as is popularly believed, but to tone up the vessel walls and stimulate the fibrous tissue formation in the area, which added strength and support to the dilated vessels, and to stimulate the sympathetic nerves, which is just the reverse of what is brought about by sympathectomy. In a case like this these three factors working together bring about a change, which prevents inflammation and tones up the dilated vessels. But there always remains a little toughness of the skin, produced by the newly formed fibrous tissue. The skin may grow unnecessarily thick, owing to excessive diathermy.

Case No. 4. Hemangioma—a pedunculated, cauliflower-like mass with a broad base, of the shape of a port-wine glass, and the size of a small lemon, growing on the right cheek of Mr. S. C. K., a Hindu male, aged 35 years. He consulted me on the 25th September, 1929.

One and a half months previously a pimple appeared on his right cheek, the contents of which he pressed out. After this it did not heal, but grew bigger and bigger. Any attempt to clean it would produce a severe hemorrhage. He was admitted as an in-patient to hospital, but refused to be operated upon in the ordinary surgical manner, as this would produce great disfigurement. Another tumour of a similar nature was

Case No. 4. First Picture. Immediately before Diathermic Treatment.

removed from the groin of the same patient in the same hospital, which on histological examination proved to be an angioma.

At the time when diathermy was first applied, 25th September, 1929, the tumour was a pedunculated, cauliflower-like mass, with a broad base, of the shape of a port-wine glass, and the size of a small lemon, growing on the right cheek, as is shown in the first picture of the case. The surface was ulcerated and the hemorrhage was profuse while changing the dressing.

In this case the methods of treating the actual growth, the pedicle, and the base were not the same. As the covering skin was lost from the distal surface of the tumour, no consideration had to be taken about preserving it. It required coagulation straight away, the intensity of which had to be varied from the surface towards the root, so that no line of demarcation or a

quick separation of the slough could take place. The treatment was repeated pretty frequently to prevent hæmorrhage, and the slough separating. The previous day's dressings were removed to such an extent as not to start bleeding. The remaining dressing was soaked with warm saline and the diathermic current switched

Case No. 4. Second Picture. Four days after the treatment.

on. After a few minutes the current was switched off, the remaining dressing could then be removed easily without disturbing the vessels. The surface of the tumour was then gently scraped, and all coagulated and dead tissues lightly separated. Then the treatment

Case No. 4. Third Picture. After seven days' Diathermic Treatment.

proper was given. As I have mentioned before, the type of current used for the fungating growth was strong enough to produce coagulation.

On the fourth day, as is shown in the illustration, I could pinch off the last portion of the out-growing

mass. The coagulated vessels with their contents could be taken out easily, like roots coming out of the ground, leaving behind a small pitted area, which is quite clear in the illustration.

From the fifth day onwards I had to use weaker currents, but for a longer duration, so as to help toning up of the vessels forming the base, as well as to produce fibrosis there. I was successful in attaining both these ends, so that by contraction the small punctured area of the stock shrivelled and disappeared, leaving practically no scar behind, and the basal portion of the growth gradually settled down without producing any breach in the skin. The only thing that remained for a time—for a month more—was a little thickening of the skin at the basal area, which could only be detected by palpation, as is shown in the third picture of the case.

Case No. 5. Cirroid Angioma of the Scalp.—21st November, 1929. Mr. R. C. C., Hindu male, age 27 years. About 28 days before, the patient noticed, while combing his hair, a red swelling of the size of a small pea on his right temporal region. No heed was given to it and it was expected that it would disappear of itself. But on the contrary it began growing in size and became darker in colour. In four weeks' time it attained the size of a big marble, when I saw him first, as is shown in the illustration. The tumour could be reduced, or the whole thing could be made to disappear under pressure and manipulation. Lately the hairs in it began to fall off and the tumour became painful and

Case No. 5. Cirroid Angioma of the scalp.

tender. Feeble pulsation could be elicited at the periphery as well as at the base of the tumour. It was closely connected with the skin, and was freely moveable over the subjacent tissues. There was no history of trauma of any kind. He had been suffering from beriberi for over two months. There were several small ones of the same type growing on different parts of his body.

I gave him two diathermies with flat electrode on the surface of the tumour. This led to a desquamation of the superficial layers of the epidermis, although the tumour dwindled in size and became firmer. I had to stop this, as a denser coagulation in the overlying thin and stretched skin might lead to sloughing, leaving an open ulcer and a liability to secondary hæmorrhage. So I tried electro- or thermo-coagulation with a needle. After three attempts the tumour became very small and very hard. About a fortnight after the last treatment

the skin became normal. No sign of tumour was there and the hair had grown again.

Case No. 6. Hemangioma.—5th January, 1930. Mr. A. C. B., Hindu male, aged 25 years. Three months previously he first noticed a pin-point red pimple on his left knee-cap which slowly grew to the size of a pea. The superjacent skin was thin and glossy. The pimple would not disappear, or alter in size under pressure. It had a cystic feel.

Three days before, while getting into a tram car, he knocked his knee and the pimple began to bleed profusely, this being controlled by sustained pressure. Since then slight friction of the clothes or slight trauma started the bleeding, which continued in like manner. Every time the hemorrhage took place the patient noticed a stout vessel running across the spot becoming prominent.

Diathermy was applied for ten minutes on the 5th January, 1930.

Such hemangiomas are usually very small things. They appear suddenly, with some preliminary irritation of the part which actually draws the attention of the patient. The full size, although very small, is attained almost all of a sudden. They remain stationary and cause no trouble in most cases. They are situated in the surface layers of the skin where there are no blood-vessels, but the bright red colour of the pimples may be due to pigment or the colour of the blood which is more related to the arterial side and constantly changing. They usually appear on the face and chest and less commonly so on any part of the body. When they appear on the knee, elbow, clavicle, or where the surface skin may be rubbed off by injury, they bleed and that profusely. This bleeding obviously proves that they are vascular things. The pathology appears to be that sprouting capillaries from the deeper layers of the skin grow towards the surface due to some stimulus, pushing through every other layer except the stratum corneum. This horny layer with a portion of the stretched out rete-mucosum forms the shiny smooth covering of the growth. The growth is too small to be broken easily, unless so situated as to be pressed between the bone and a hard substance.

After the single treatment given he never bled since, though it was as much open to injury as before. Next day half of the growth was filled with coagulated blood and in ten days' time the whole growth was replaced by a crust. This crust in four or five days' time fell out as a scab, leaving a perfectly normal surface level with the surrounding skin.

PETROL DERMATITIS.

By M. M. CRUICKSHANK, M.D., CH.M.,

MAJOR, I.M.S.,

and

P. P. CHOWDRY, M.B., B.S.,

CAPTAIN, I.M.S.,

Quetta.

THE literature dealing with petrol dermatitis, or with burns due to prolonged immersion in petrol, or to prolonged exposure to petrol vapour is singularly scanty.

We have been able to find only two references to such, and the Gas School at Belgaum could produce nothing on the subject. The following case is therefore of interest.

A coolie while working at the manhole of a large petrol tank, apparently overcome by the petrol fumes, fell into the tank, the bottom of which was covered with petrol to a depth of not more than two inches. Two men in the vicinity of the tank failed to get the coolie out on account of the suffocating effect of the

petrol vapour. One hour later an N. C. O. of the R. A. M. C., wearing a gas mask, entered the tank, tied a rope round the man's body, and thus he was eventually got out. The man was at once taken to the Indian Military Hospital, Quetta.

On admission he was quite unconscious, pulse imperceptible, breathing laboured.

Blisters, most of which had burst, had already formed on every part of his body, much more than half the superficial skin area being burnt.

The patient was placed in the open, the little clothing he had removed, and oxygen inhalations with injections of strychnine and digitalin given.

The patient was wearing cotton pyjamas, a cotton shirt and a waistcoat, all of which were soaked in petrol.

At 4 p.m., five hours after being removed from the tank, he regained consciousness, was very restless and complained of severe thirst, to relieve which he was given copious draughts of water. His pulse, 80 per minute, improved in volume and tension. Temperature 97° F.; respirations 22 per minute. There were no signs of oedema of the larynx, the lungs were clear, and urine was passed freely and was free from albumin.

The patient made no complaint of pain.

The burns, which were of the second degree, were dressed with half per cent. picric acid solution.

The following morning the patient was comfortable, the lungs were clear and the urine free from any trace of albumin.

Small discrete ulcers were seen to be forming on both cornea.

On the third day the patient seemed to be progressing favourably, but the onset of severe diarrhoea, which was readily controlled with bismuth salicylate, added to his discomfort.

On the fourth day the eye condition was much worse, the eyes presenting the appearance of a traumatic conjunctivitis with lachrymation and photophobia, with superimposed dermatitis of the lids. The dull greyish white necrosed areas on the cornea spread until the whole surface of both cornea was involved. Despite deep ulceration perforation did not occur, but there was considerable shrinking of the eye balls, which before death presented an appearance similar to that which one associates with old blind eyes.

On the fifth day the general condition of the patient was very much worse; and from that date he went rapidly down hill, and died on the ninth day.

After the preliminary dressing with picric acid No. 7 paraffin was used, but it was very evident that the change to the oily dressing produced marked irritation, the patient constantly attempting to remove these dressings. The fact that oily dressings cause pain in these cases was noted by Page.

That any part of the skin condition was due to prolonged exposure to petrol vapour alone is very unlikely, because the unfortunate man may have rolled about in two inches of petrol before becoming completely unconscious.

The cause of death may have been due to a toxæmia the result of sepsis, or the direct result of poisoning by petrol absorbed and inhaled. Petrol is a complex mixture of the lighter series of hydrocarbons and among the symptoms of poisoning by petrol are a feeble pulse, insatiable thirst and restlessness at night, all noted in the case described.

Page (Petrol Dermatitis, *Practitioner*, 1918), who, during two years with the Royal Naval Air Service in Flanders, saw numerous cases,

states that the lesions resemble burns of the first and second degree, that is to say, there is erythema with some vesication, with a considerable amount of pain. His treatment consisted in the use of lead lotion or of zinc carbolie lotion (zinc oxide drs. 3, suspended with glycerine ozs. 1 in 1 per cent. carbolie acid solution to ozs. 8), applied on lint or sponged on. He points out that grease of any sort increases the discomfort. As the symptoms subside, which he states they rapidly do, a simple dusting powder is used, the affected parts being left uncovered in warm weather, a cradle being used to support blankets if these must be used.

Schwald (Verätzung durch Benzin, *Deutsche Med. Wochenschrift*, 1913, August) states that benzine causes marked erosion and even necrosis if brought into contact with the skin in such a way that its evaporation is prevented or delayed. This, he points out, has been observed in cases of abdominal operations when part of the benzine used for disinfection flowed down to the sacral region, to the buttocks and behind the thighs where it could not readily evaporate. The effect was also noted when lumbar puncture wounds were covered with gauze saturated in benzine and fixed with adhesive tape; also in cleaning the lobe of the ear with benzine when some of it flowed into the ear giving rise after a few minutes to severe pain. As he points out, no therapeutic use has yet been made of this property of benzine.

SOME OBSERVATIONS ON THE PREPARATION AND EXAMINATION OF THICK FILMS FOR MALARIA PARASITES.

By R. A. MURPHY, L.R.C.P. & S.I.,
Luskerpore Valley Medical Association,
Chandpur Bagan P. O., South Sylhet.

IN a country such as Assam where malaria is endemic it is imperative for the doctor to ascertain whether his patient is infected with the parasite of this disease, even although such may not be the primary cause of the illness. The information however, can only be conclusively obtained from blood films, and if these cannot be prepared and examined with confidence, the patient will suffer from the lack of a precise diagnosis.

In the days when only thin films were used, findings used to be somewhat discouraging, for hours might be expended on some preparation, and nothing found, although the diagnosis was clearly malaria, confirmed, perhaps, by films taken subsequently.

The introduction of the thick film method marked a great advance, for although it has difficulties of its own, and some experience is required to make good use of it, the infections are few in which it is not possible to ascertain within a very few minutes that parasites are

present, even though the appearance may not be very typical, nor the species a certainty.

The rapidity with which parasites can be found in thick films is not entirely due to the greater quantity of blood which can be examined in a given time, but is largely due to the fact that fields can be rapidly passed over, the parasites standing out so definitely on the clear, or faintly stained background. Moreover, the parasites most likely to be missed in a thin film are the small *P. falciparum* rings, either because, on account of their minuteness, they require careful focussing to pick them up, or because they sometimes take the stain badly. But in a thick film they stain well, and the ring appearance is better preserved. Not infrequently the thick film will show the young rings of this species in large numbers, and yet in the thin film they will only be seen with great difficulty, or may appear not to have taken the stain at all. The Romanowsky stain in the hands of the expert in a laboratory may be absolutely reliable, but in general use it is fickle, and the causes are hard to find. One part of a thin film may show well-stained parasites, while in another part they are not stained at all.

One of the simplest methods, and suitable for those in general practice, is to make the thick film at one end of a slide, and make also a thin film on the same slide, about three quarters of an inch separating the two films. The thick film may be made by taking four drops of blood and joining them, as generally advised, but quite good results can be got by taking one large drop and spreading it to the correct thickness. It should be especially thinned out at the edges, and young parasites will be best seen there. To stain, the films are divided by a grease line, and after double the quantity of water has been mixed with Romanowsky stain on the thin film, it is drawn over the line on to the thick.

It cannot be over-emphasised that to get the best results with thick films they must not be too thick, and they must be clean. It is difficult to define the required thickness, but when stained the thick film should appear to the naked eye very little thicker than the thin. The care necessary for the cleanliness requisite is not easy to teach to some, but the method largely loses its value if continual halts have to be made to examine foreign matter. The films must be very carefully protected, especially while drying, against dust and insects.

In thicker parts of a film the young *P. falciparum* rings do not show up well, but may be spotted as faint blue rings. In the thinner parts they are seen with great distinctness, both nucleus and protoplasm deeply stained, making well-formed rings. The large number, early division of the nucleus, and small size help to indicate the species. Other species do not show such small delicate rings, but

P. falciparum may on occasion show up as fairly large substantial looking rings. Older forms are not uncommonly seen in thick films, and, as pointed out by Knowles, even the sporulating stage is not infrequent, and these are quickly picked up by the small compact mass of pigment. The spores may be well-stained in every detail, or only pigment and protoplasm may be apparent. These older forms can with diligence often be confirmed in the thin film, and one of the advantages of the thick film is that it quickly indicates whether a prolonged search of the thin film is likely to be rewarded. Incidentally, this also holds for *Piroplasma* infection in animals. It is well to bear in mind that the more mature forms of *P. falciparum* may be found, or they are liable to be mis-called *P. malariae*.

Crescents are easily detected, but may appear foreshortened, even to the extent of a round mass of protoplasm surrounding the pigment, and then may be mistaken for sporulating parasites, but the pigment is more diffuse than in the latter. The ingested pigment of the mature schizont is shown very strikingly in the leucocytes, and the little mass with its characteristic size, shape and hue is unmistakable. In heavy infections this pigment may be so plentiful that at first glance the film might be condemned as dirty.

P. vivax appears according to type, but where a film is too thick only the protoplasm may be obvious, and in half-grown parasites this may be broken up into two or more rounded blue masses. The larger size of this species, and the fine light brown pigment, are distinctive, and the pigment contrasts strongly with the heavy black pigment of *P. malariae*.

Diagnosis of species from thick films alone does not come easily at first, but as experience is gained most parasites can be placed correctly. If one film is used as a complement of the other, the proportion of error remaining will not be sufficient to invalidate percentages drawn from a series of observations.

ON THE ROLE OF *ARGAS PERSICUS* OKU, IN THE TRANSMISSION OF *PASTEUR-ELLA AVICIDA*.

By B. C. BASU, M.Sc.,

Entomologist, Spirochaetosis Transmission Enquiry,
Calcutta School of Tropical Medicine.

Pasteurella avicida is the causative organism of chicken cholera or fowl plague, which frequently affects these birds in sudden epidemic form.

Moritz in 1869 first noticed certain "granulations" as he termed them, in the bodies of birds which had died from this disease. Nine years later Perroncito sketched the microbe. Detailed observations were not made on this disease until 1879-80, when Toussaint demonstrated that a microbe was the cause of the infectivity of the blood, and Pasteur observed

that birds, when fed upon the smallest drop of a recent culture of the micro-organism, became infected via the alimentary canal, and that the infected excreta were a cause of contagion to clean fowls.

In the present paper the writer gives the results of observations made in 1928 as to the rôle of ectoparasites of fowls in the transmission of this disease. For this purpose the common fowl ticks, *Argas persicus* Oku, were collected from Calcutta fowl houses, and fed on birds infected with *Pasteurella avicida*. In order to infect the fowls, as a rule 200 million *Pasteurella* from a 24-hour culture were inoculated intravenously. Invariably, as tested in ten fowls, *Pasteurella* was isolated in blood cultures from such inoculated birds, ten hours after the intravenous injection.

Eight "clean" fowls were taken, and blood cultures taken from each to make certain that they were free from *Pasteurella* infection; in all, the cultures remained sterile. These eight birds were now made to ingest ticks, which had been fed from 1 to 20 days previously on fowls suffering from *Pasteurella* infection. After this the blood of each fowl was cultured daily till the bird died.

Of these 8 birds, 1 died the day after the injection. Of the remaining 7, 2 became infected. One bird, which had ingested 30 ticks fed 4 days previously on a *Pasteurella*-infected bird, became infected 3 days after swallowing the infected ticks; and the second fowl, which had ingested 50 ticks fed 1 day previously on a *Pasteurella*-infected bird, became infected on the second day after the feed. Fowls thus infected lived as long as 7 days after the first appearance of *Pasteurella* infection in the blood stream, whereas, on the other hand, birds inoculated intravenously with culture usually die within six hours or so of the injection, which proves rapidly fatal. (In all these experiments care was taken that there should be no chance of the birds becoming infected by the dejecta of infected birds contaminating their cages or food, and being swallowed.)

In Nature fowls are rather fond of picking up and eating ticks, and it seems possible that *Pasteurella* infection might be acquired in this manner. On the other hand naturally acquired *Pasteurella* infections are apt to be extremely virulent and to kill rapidly, whereas the infections contracted by ingesting infected ticks are milder and less rapidly fatal. It would appear that there is some loss of virulence of *Pasteurella avicida* in the gut of *Argas persicus*.

Cimex hemiptera, the common bed-bug is frequently found in fowl houses and feeds readily on fowls. Experiments were carried out to see whether it was possible for *Pasteurella* infection to be acquired by ingesting infected bed-bugs. Three clean fowls were made to swallow bed-bugs fed from 1 to 3 days previously on *Pasteurella*-infected birds. None of them became infected. It seems probable that

Pasteurella avicida does not survive in the viscera of *Cimex hemiptera*. (As is well known, the bed-bug is a pure blood feeder, and the contents of its gut are bacteriologically sterile; possibly its gut may contain bactericidal principles.)

Further experiments were also carried out to see whether these ectoparasites could convey the infection by their bite. The blood of 7 clean fowls was cultured in order to make certain that they were free from *Pasteurella* infection; all the cultures remained sterile. Ticks, fed from 1 to 41 days previously on *Pasteurella*-infected birds, were next re-fed upon these seven fowls. After this the blood of each bird was cultured daily. Out of the 7 birds only 1 became infected, the incubation period being 2 days. This was a bird, which had been bitten by ticks which had bitten the *Pasteurella*-infected birds 14 days previously. Results in the case of this bird appear to be rather anomalous, and it is difficult to say definitely what was the mode of infection in this case.

Bed-bugs (*Cimex hemiptera*) fed 3 days previously on *Pasteurella*-infected birds were re-fed on 2 clean fowls (whose blood had been previously cultured and had been proved to be free from *Pasteurella* infection). Neither bird contracted the disease. It would appear that the bed-bug is a much less hospitable host to *Pasteurella avicida* than is *Argas persicus*.

The causation of epidemics of fowl cholera gives great scope for investigation, and the question is of great economic interest. Pasteur, as well as several other eminent observers, noted that the onset of these epidemics is always sudden. The question naturally arises as to what is the source of infection in such explosive outbreaks. During the outbreak, infection usually spreads via the contaminative route, the food of clean fowls becoming infected with the dejecta of infected birds. This holds good for the spread of the epidemic, but will it account for its origin and sudden appearance? *Pasteurella avicida* is a very delicate organism; it is easily killed by desiccation, by heating to 55°C., by antiseptics, and by very dilute acids; it does not form spores; therefore *Pasteurella* organisms passed in the faeces of infected birds on to the soil are not likely to survive for long under ordinary conditions of atmospheric temperature and humidity.

The question arises whether infection may persist in the off-season in the invertebrate host, *Argas persicus*, and the onset of the epidemic be initiated by the ingestion of infected fowls ticks by clean fowls. Kelser (1927) theorises as follows:—"Organisms of the *Pasteurella* genus are widely distributed in Nature. They are very frequently found in the upper air passages of normal cattle, horses, swine, sheep, dogs and cats. Less frequently they are found as normal inhabitants of the intestinal tract. Thus in a way they are more or less facultative pathogenic bacteria, being present

in normal animals, and only producing disease when the normal resistance of the animal is lowered, or following a particular increase in the virulence of the organism, which in some unknown way seems to occur."

My thanks are due to Dr. B. M. Das Gupta, Assistant Professor of Protozoology, Calcutta School of Tropical Medicine, for much valuable help received during the course of these investigations.

A Mirror of Hospital Practice.

AN EXTRAORDINARY CASE OF SELF-MUTILATION.

By H. R. SHARMA, L.M.P.,

Sub-Assistant Surgeon, Civil Hospital, Kalewa (Upper Chindwin).

M. T. M., aged 27, of Kywe Chan village, was brought to the Civil Hospital, Kalewa, on 22nd September, 1929, at 9 p.m. in a moribund condition. He died within half an hour of the time of admission.

History of the Case.—The father-in-law of the patient stated that the latter had been suffering from inguinal hernia since childhood. At times it could not be reduced without great difficulty. On 22nd September, 1929, the hernia became strangulated and the patient made up his mind to do away with the offending part, which was so troublesome to him every now and then.

He was left alone upstairs as no human help was thought possible. In an extremely emotional state and in agony he picked up his *dah*, seated himself with stretched legs and made a bold cut on the right scrotum, 3½ inches long vertically. The innocent testicle which happened to appear first from underneath the skin was readily severed. By the release of the strangulation due to the incision, the omentum and intestines, finding a vacancy in the scrotal cavity, made their appearance through the wound and unfortunately met the same fate as the testicle. This caused some pain to the patient and so, it is said, he screamed. On enquiry from his relatives who were sitting downstairs, he replied that nothing was wrong. The intestines were obstinate and the "surgeon" was determined, so the latter went on cutting the former piece by piece, until seven pieces of the gut had been cut off, measuring 39 inches in all. When tired of cutting the gut like this the deceased attempted to pull out the whole of the offending part and cut, unsuccessfully, a piece of gut 5 feet 8 inches long. At this point the people sitting downstairs were alarmed by seeing blood streaming from above, and rushed upstairs. In fact the last attempt was unsuccessful because of their interference. Here ended the operation. The last piece of the intestines either receded by itself or was pushed back by the new arrivals. This was found next morning at autopsy. The peritoneal cavity had now become the receptacle of the cut intestines, blood and various other discharges, the natural machinery of the abdominal cavity being upset altogether.

The relatives, being afraid of the authorities, were in an awkward position, and the hospital was thought

of as the only possible shelter, so the patient, with the cut pieces, was wrapped in an old mat and brought to Kalewa to die.

On arrival in the hospital he was cold, air-hungry, extremely pale and pulseless. He was conscious, but unable to speak.

A CASE OF AGRANULOCYTIC ANGINA.

By R. VISWANATHAN, B.A., M.B., B.S.,

Assistant to Professor of Medicine and Assistant to First Physician, General Hospital, Madras.

SCHULTZ in 1922 described a form of angina with necrosis of the tonsils and pharynx associated with a decided leucopenia, especially of the granulocytes. He classified this symptom-complex as a separate disease which he called "agranulocytosis." Since then more than 120 cases have been recorded under this name. Heuper has reported five cases between November 1927 and April 1928, while more recently Bocage and Filliol have described a fatal instance of agranulocytosis in a case of syphilis.

The aetiology of the condition is unknown, though most investigators are agreed in regarding it as an infectious disease of a septicæmic nature "with an atypical reaction of the hæmopoietic system due either to bacteria with a special affinity and toxicity to the granulocytic system or to an atrophy and aplasia of this organ caused by septic infection." In the case reported by Bocage and Filliol they found at necropsy the characteristic changes in the bone marrow cells described by Schultz, along with a large number of a Gram-positive micro-organism resembling *B. perfringens*. It has not been possible to incriminate one particular bacterium as to the cause of this disease since other organisms such as *Streptococcus hemolyticus*, *B. pyocyaneus*, etc., have been isolated in other cases where the same group of symptoms going under the name of "agranulocytic angina" was manifested.

The disease usually affects the middle-aged and is more common in women than in men. It often starts suddenly in previously healthy people. It also occurs in debilitated individuals after a period of prolonged ill-health, as in the case of Bocage and Filliol, where the necrotic pharyngitis started in an anæmic man after a course of N.A.B. and bismuth injections. It is accompanied by high continuous fever, dysphagia and dyspnoea. The tonsils are enlarged and hyperæmic and subsequently become necrotic. The pharynx and lingual tonsils may also suffer the same fate. Sometimes the necrotic process is found in the tongue, gums, anus, vulva, vagina and cervix. The chief characteristic is the blood picture which shows considerable leucopenia, the granulocytic cells being the first to diminish. Prognosis is gloomy in the extreme though not absolutely hopeless.

I am reporting the following case because it was very suggestive of agranulocytic angina:—

An Anglo-Indian male, aged 20 years, was admitted as an in-patient in the Government Head-quarters

Hospital, Coimbatore, on 20th November, 1928, for high fever and difficulty in swallowing. He had a temperature of 102°, pulse 98, and respiration 28. The inside of the mouth presented a very unusual appearance. Both tonsils were enlarged, almost greenish blue in colour owing to evident necrosis. The posterior wall of the pharynx was also in the same condition, while there was a patch of submucous hæmorrhage over the palate and uvula. There was bleeding from the gums as well as the tonsils. There was no enlargement of lymphatic glands. Examination of a throat swab revealed the presence of long-chained *Streptococcus hemolyticus* and no diphtheria bacilli. The blood showed marked leucopenia. The leucocyte count was below 1,500. There was relative diminution of polymorphonuclears. There was no enlargement of the lymphatic glands. The spleen and liver were not palpable.

On the second day the temperature went up to 101° and dysphagia was so great that it prevented the patient from taking even liquids. He also developed purpuric eruptions all over the body and complained of pain over the bones of the thighs and legs. The condition was decidedly one of a severe form of septicæmia. He was put on to injections of anti-streptococcal serum, calcium by the mouth, calcium by injection and stimulants such as glucose and brandy. After oscillating between life and death for some days, the patient began to improve, the temperature came down gradually, accompanied by slow separation of sloughs from the tonsils and pharynx. The temperature touched normal on the 16th day and the patient was discharged from the hospital on 13th December, 1928.

On making enquiries about the patient two months later we were reliably informed that the patient developed the same symptoms in a more virulent form some fifteen days after being discharged from the hospital and succumbed to the disease in the course of two days.

The possibilities in this case are aleukæmic leukaemia and agranulocytic angina. Diphtheria is ruled out because of the negative throat swab and fatal relapse, which is an almost unknown phenomenon in diphtheria. Against aleukæmic leukaemia, we have the absence of enlargement of the liver and spleen and lymphatic glands. Besides the duration of the disease is too short even for acute leukaemia.

The characteristic signs which suggest strongly the possibility of agranulocytosis are the necrotic condition of the tonsils and pharynx, bleeding from the gums, purpuric eruptions, pains over the long bones and high continuous fever associated with a blood picture of distinct leucopenia, especially of the granulocytes, and a fatal relapse occurring a few days after the termination of the primary attack.

UNUSUAL SYMPTOMS IN A CASE OF ROUND-WORM INFECTION.

By S. S. PATTANAIK, L.M.F. (Cal.),
Medical Officer, Piple, Puri District.

A SHORT time ago I was called in to see a patient in a village.

On visiting the place, I examined the patient. He was a boy about 10 years old, neither well nourished nor well developed. He had been suffering from purging and vomiting for the last two days and was in a condition of extreme prostration. He was very restless and was slightly delirious. He complained of a rather dull aching pain in the abdomen. Being a boy of only 10 years, he could not give a full account

of his sufferings, nor could he explain the exact nature of his ailments.

On examining I found the tongue was moist, eyes presenting an anxious look, pulse more or less sinking. Temperature: 102°; abdomen tympanitic and tender. During my examination the patient passed a loose watery motion, yellowish in colour and slightly frothy. I had no opportunity to see the vomited matter.

At the outset, I was inclined to think that the case was one of poisoning. The parents could give me no clue regarding my suspicion nor did they suspect of anything of the kind.

As the patient was in a state of impending collapse, to combat it an injection of digitalis and strychnin was given and a dose of stimulant administered.

Cold sponging over the forehead was ordered for controlling the delirium. Afterwards the patient was put on a mixture containing some mild astringents and earminatives; the mixture was supplemented by three powders containing intestinal antiseptics.

The next morning it was reported that the medicines had not succeeded in checking the vomiting and purging, though the delirium had subsided to some extent.

I was then told by the father of the patient that the boy had passed a big worm a week prior to his present troubles. This led me to suspect him to be a victim to intestinal worms. Accordingly I ordered a full dose of santolin followed by a dose of castor oil after an interval of three to four hours.

To my surprise, I was told in the evening that the patient passed 9 or 10 big round-worms—one coming out by the mouth.

Gradually after this the distressing symptoms began to subside. It was reported the next day that the patient was apparently relieved of all his ailments, with the exception that he felt very weak.

Conclusion.—There seems to be little doubt that unusual symptoms in this case were due to the round-worm infection.

THREE CASES OF SALIVARY CALCULUS.

By MILITARY ASSISTANT SURGEON C. D. TORPY, I.M.D.,
British Military Hospital, Trimulgherry (Deccan).

SALIVARY calculus is treated in most text-books of surgery as a "rara avis." It is certainly not a very common disease, hence it is hoped that no apology is required for the publication of a few notes on three successive cases met with in the short space of two months.

The three cases that follow were all British soldiers, under twenty-five years of age, leading an active and healthy life, drinking the same water, and living on much the same diet. In all three cases, the dental condition was very good there being a total absence of any tartar formation, or evidence of pyorrhea. None of them was a total abstainer, and all drank a certain amount of beer. Only one of them gave a previous history of calculus formation in the parotid gland during childhood.

1. *Private L.*—First reported sick with a painful, enlarged swelling "in his neck, beneath the right jaw." There was some discomfort, and pain in opening his mouth. Owing to the prevalence of "mumps" at the time, it was thought to be a case of unilateral mumps. He was isolated and treated as such. He was finally discharged after a month as "cured."

He was only a fortnight out of hospital when the symptoms reappeared. In addition to the previous enlarged swelling in his neck, he complained of a copious discharge of muco-pus into his mouth. The sub-lingual papilla appeared swollen and red, while the

mucous membrane of the floor of the mouth was also red and oedematous. X-ray findings were negative.

The patient was placed on hot saline mouth washes every hour. Later, under general anaesthesia, an incision was made inside his mouth, and the abscess opened with a pair of sinus forceps. A good deal of offensive muco-pus drained away. The calculus was felt within the duct, and portions were removed. Hot saline mouth washes were continued, and the patient made an uneventful recovery. No recurrence has since been observed.

2. *Private F.*—Reported sick with all the signs and symptoms of a submaxillary salivary calculus on the right side. No calculus could be felt, but x-ray findings were positive.

He was put on hot saline mouth washes frequently; later on incision was made inside his mouth, and the pus evacuated. The calculus was felt lying within the duct, but all attempts to remove it proved futile. Saline mouth washes were continued, and the patient was greatly relieved. In a few days time the symptoms all re-appeared and it was decided that excision of the gland was necessary. Under a local anaesthetic, a curved incision was made above the hyoid bone, and the submaxillary gland removed *in toto*. The patient made an uninterrupted recovery, and was discharged fit.

3. *Trooper W.*—Reported sick with a painful and enlarged right submaxillary gland, and offensive muco-pus discharge into his mouth. A calculus was felt projecting at the entrance of the duct; x-ray findings were negative. Hot saline mouth washes were given every hour, and the next day, much to the surprise of the patient, and his nursing attendant, he spat out the offending body, and made a speedy recovery. He was discharged as apparently cured.

After an interval of three months, free from all symptoms, the patient reported sick with the same condition on the same side. Excision of the gland was done, and the patient discharged fit.

The following are the points of interest in these cases:—

1. The sudden occurrence of three cases of salivary calculus within the short space of two months—and confined to British troops only.

2. The difficulty experienced in locating, and removing the calculus.

3. Simple incision within the mouth, with drainage, sufficed to abate all symptoms of the disease.

4. Radiological findings were positive in one case only.

5. Even when all evidence of calculi are removed it is not possible to forecast a cure. Excision of the gland was necessary to cure two of the three cases.

6. All three cases were of the submaxillary type.

My grateful thanks are due to the Officer Commanding, the British Military Hospital, Trimulgherry, and to the Surgical Specialist, for their kind permission to publish these notes.

A CASE OF AMOEBI ABSCCESS OF LIVER.

By P. ARUNACHALAM, M.D.,

Assistant to the Second Physician, King George's Hospital, Vizagapatam.

BHADRI, a Bhairagi, male, Hindu, 35 years, was admitted into the King George's Hospital, Vizagapatam, on 21st October, 1929, for amoebic abscess of the liver, duration two months. The liver was considerably enlarged, the lower border being 10 inches from

the right nipple in the nipple line. The patient's temperature was between 99° and 102°F. for two days after admission. He was given injections of emetine hydrochloride one grain each for nine consecutive days. The general condition improved remarkably and the local pain and tenderness were considerably less, but, as the liver showed no signs of any diminution in size and it was feared that the abscess might burst into the peritoneal cavity, it was decided to aspirate the liver. Major F. J. Anderson, M.C., R.M.C.S., I.M.S., aspirated the abscess on 6th November, 1929, and 81 ounces of thick "pus" were drawn out. The patient has been doing quite well since.

AN UNUSUAL FRACTURE.

By R. P. WELDON.

Chief Medical Officer, Assam-Bengal Railway Co., Ltd., Chittagong.

THE following seems to be a sufficiently rare accident to be worthy of record:—

Miss X., aged 39 years, was thrown from her horse and fell on hard dry ground paddy stubble. She felt severe pain in the right shoulder and right side. She was conveyed to the Railway Cottage Hospital, Chittagong, and was seen by me immediately on her arrival.

From the marks on the clothing, it was evident that the right side of the head, the right shoulder and to a lesser extent the right side, had come into more or less violent contact with the ground.

The pain in the shoulder was most marked at the root of the neck posteriorly. Movement of the shoulder caused pain and there was complete inability to raise the right arm to shoulder level.

Examination revealed fractures of the fifth and sixth ribs on the right side, but no fracture or dislocation of the arm or shoulder girdle could be palpated. The fractured ribs were strapped in the usual manner and she was put to bed.

Next day, as the pain in the shoulder was still acute, a skiagram of the shoulder girdle was taken. The film showed a fracture of the first rib at the junction of the posterior and middle thirds.

Recovery was unevenful, but full movement of the arm was not established for five weeks.

Fractures of the first rib are rare. It appears probable that in this case the fracture was caused by direct violence against a stone or hard lump of earth.

QUININE "ADDICTION."

By S. C. NAG,

In-Charge Barbheel T. E. Hospital.

Borgong P. O. Tezpur, Assam.

CASES of cocaine or opium habit are not rare in general practice, but those of quinine habit are perhaps exceptional. The writer, however, has seen in his 19 years' practice two cases in which quinine rendered the users so much addicted, that they only gave up the habit with much difficulty. The histories are given below:—

Case 1.—Mrs. B., age 28, wife of a revenue officer, said to have suffered from chronic malaria, following her attending physician's advice, had regularly taken a 5-grain quinine tablet with tea between 3 and 4 p.m. once daily for a few months. Once there was no quinine tablet in stock and the lady could not take the daily dose for 3 or 4 days with the result that on each of these days, about an hour after quinine was due but

was missed, the lady experienced headache, and uneasiness, the cause of which was wrongly attributed to a slight malarial attack. Thereafter another supply of quinine tablets was procured, which the patient again took regularly as before, for about a year. When these tablets were all consumed the patient again had none to take for a couple of days with the result that shortly after the usual time at which quinine was due but was not taken, the lady felt so much headache and uneasiness that she could not look after her domestic affairs. This time also the trouble was attributed to malaria excited by failure to take quinine.

Then the writer was consulted and something to eradicate the "supposed" malaria was asked for. A report from the family physician and a detailed history of the case disclosed that the lady had had no malaria for about a year, and that quinine was continued during this period not only as a preventive measure, but also because the patient did not feel well without it. Though I found it difficult to attribute a cause to headache and uneasiness, I advised the lady to stop quinine. This she did with the effect that, after about a week's suffering from headache and uneasiness daily at the same time of day, the lady did not feel any more inconvenience.

Case 2.—K. C. S., male, aged 40, sought the writer's advice for the sense of depression with feverishness, headache and chilliness, experienced within an hour after missing the daily doses of quinine, which had been taken in 5 gr. doses (in tablet form) twice daily with tea—once between 8 and 9 a.m. and once between 5 and 6 p.m.—for a period of about four years, as a malaria preventive, according to a friend's advice. He said that during the first year of this quinine course he did not feel worse for the occasional omission of quinine, but from the second year he experienced the above trouble whenever he failed to take the drug. The history of the case at once reminded me of the case of the lady reported above, and I told him to stop quinine and not to apprehend trouble from omitting the drug. Accordingly he stopped quinine, and, though for the first two weeks or so he was much inconvenienced, he felt no trouble after that period.

SCIRRHUS CANCER OF THE BREAST IN THE MALE.

By CAPTAIN MOHD. AJMAL HUSAIN, P.C.M.S.,

Assistant Surgeon, King Edward Memorial Hospital, Karnal.

S. HINDU male, aged about 60 years, resident of Karnal District, was admitted to the King Edward Memorial Hospital, Karnal, on 23rd March, 1930, with a fungating growth of the right breast about the size of a medium-sized orange. Duration—about one year, rapidly growing for the last 3 or 4 months. The skin over the growth was very thick and adherent. The growth was almost stony hard in consistency, and slightly moveable over the deeper structures. The glands in the axilla were palpable and hard in character.

Provisional Diagnosis.—Scirrhous cancer of the breast.

Operation.—Under chloroform, complete amputation of the breast with the portion of the pectoralis major underlying and adherent to the growth, as well as removal of enlarged lymphatic glands, was carried out.

Examination of Growth.—The Bacteriologist to the Punjab Government reported the microscopic appearances as a typical scirrhous carcinoma.

Result.—Healing by first intention ensued except in the centre of the line of incision to the extent of about an inch, in which area the edges are gaping probably due to the tension of the flaps. This area is healing by granulation.

The writer of this note is indebted to Dr. A. F. J. D'Arcy, Civil Surgeon, Karnal, for kindly suggesting and permitting him to send these lines to the *Indian Medical Gazette*.

JUNE.

THE CHOLERA BACTERIOPHAGE.

MANY hard things have been said about Bengal, but no accusation hurts us quite so much as one which we know, or at least suspect, to be true. Whenever cholera is mentioned sanitarians the world over point the accusing finger at Bengal. There may be other endemic foci of the disease, there is almost certainly one in Indo-China, but the historical epidemics have all been traced to Bengal. The facts are very difficult to deny. Whenever there is an outbreak of cholera in any other part of the world, or even of India, it may last a few months, or even a year or two, but eventually it completely disappears, whereas in Bengal month in and month out cholera is with us; it would in fact be quite safe to say that on every day in every year somebody in Bengal dies of this disease. What is the reason for this? Many have been suggested. Some observers claim that it is entirely due to the peculiar climatic conditions, others blame the religious customs of the people, and yet others consider that it is due to the existence of a large number of carriers. However, recently, there has been a general agreement that it is probably due to a combination of a number of factors: the climate, which is undoubtedly favourable to the extracorporeal existence of the vibrio, the habits of the people, washing in tanks and then drinking the water, the existence of a large number of carriers and the frequent pilgrimages which disseminate the infection both within the province as well as outside it. In a *Memoir of the Indian Journal of Medical Research*, just published, Dr. d'Herelle, Major Malone and Dr. Lahiri have given another theory for this endemicity.

To understand this theory it is necessary to know something of the natural history of the cholera vibrio, more especially regarding its reaction to the bacteriophage. The authors in this memoir have not run any risk with their readers and the first part of the memoir would constitute an excellent primer in the study of bacteriophage. Not only are the nature and the mode of action of the bacteriophage described in detail, but throughout numerous examples are given to demonstrate each step in the theory of bacteriophage as applied to the cholera vibrio. The virulence of a vibrio, or of any other micro-organism for that matter, may be considered as its power to secrete a proteolytic enzyme, which has the power of making

the body tissues (the intestinal mucous membrane in this case) fit for assimilation by the micro-organism. This virulence may be lost in one of two ways, (a) through disuse, in which case the loss is usually incomplete, and is in any case not permanent, or (b) by mutation following the action of the bacteriophage on a virulent strain of vibrio; in the latter case the loss of virulence is apparently permanent. When a vibrio remains outside the body tissue for any length of time, either in nature or *in vitro*, it tends to lose its virulence and if ingested might give rise to no symptoms, or at the most to a vibronic diarrhoea, but after passage through one or two persons its virulence would be regained to its fullest degree. In every human intestine there is present an ultra-microscopic organism, the bacteriophage, which parasitizes the normal bacteria of the intestine, but when the intestine is invaded by the cholera vibrio this bacteriophage is capable of adapting itself to parasitization of the new invader; the rapidity with which this occurs depends on the conditions present in the bowel, slight alkalinity for example favours the bacteriophage whereas acid retards its development. So that when a person is attacked by cholera one of three things occur: (i) the bacteriophage fails to adapt itself sufficiently quickly, the multiplication of the vibrio is unchecked, and the patient dies of the disease; (ii) the bacteriophage multiplies rapidly, completely overcomes and destroys the cholera vibrios and the patient recovers; or (iii) the bacteriophage attacks the vibrio but, although not completely destroying it, modifies its character to such an extent that it undergoes mutation and becomes avirulent and again the patient recovers. The vibrios that have undergone mutation d'Herelle and his co-workers refer to as degenerated vibrios and they claim that under ordinary circumstances they never recover their virulence, that is the mutation is irreversible. In the test tube these avirulent vibrios can be produced by the action of a suitable bacteriophage on a vibrio culture; under these conditions they are referred to as secondary cultures. Under the insanitary conditions under which most of the victims of cholera live, the patient who dies disseminates virulent cholera vibrios, but the patient who survives disseminates bacteriophage adapted to parasitization of the cholera vibrio, as well as in some instances avirulent cholera vibrios; thus as the epidemic progresses some of the persons, who ingest cholera vibrios, have previously been infected by the bacteriophage already adapted to parasitize the cholera vibrio; in such persons the bacteriophage has a fair start, it almost invariably defeats the vibrio, consequently as time goes on the recovery rate in an epidemic increases, and finally when the whole population is infected with the specific bacteriophage the epidemic comes to an end. At this stage if the water supply

in the vicinity is examined it will be found to contain a large number of vibrios, these are avirulent and non-agglutinating, or only agglutinating in a very low titre.

Now, according to d'Herelle and his co-workers, the difference between the endemic and the non-endemic, or epidemic, areas is that whereas in the latter the degenerated vibrio never regains its virulence and therefore the disease disappears until it is again re-imported by an infected person arriving in the locality, in the former for some reason or other the degenerated vibrio regains its virulence. They suggest that at the bottom of the ubiquitous tank in Bengal lies the secret to the problem of the endemicity of cholera. At what this secret is they only guess; they suggest that in the intestines of some aquatic animal, annelid, crustacean or mollusc, the degenerated vibrio is capable of regeneration.

The authors of this memoir not only produce an entirely new theory regarding the epidemiology of cholera, but they are very destructive in their criticism of old theories and practices. In some cases their arguments are very convincing, as for example in their condemnation of the practice of permanganating wells; they point out that unless this is done much more thoroughly than it is done in actual practice, it does not destroy the vibrios present, that whenever a well is permanganated the people do not use it but use instead water from any tank or stream in the locality which is often far more highly polluted, that permanganate tends to kill the bacteriophage which would normally help to end the epidemic, and finally that it is a very unpopular measure which tends to make the people averse to all other sanitary measures; also in their criticism of the carrier theory of the spread of the disease which is dependent on one single, and according to them fallacious, observation made by Greig in Puri. On the other hand their summary dismissal of Rogers' hypertonic saline treatment with the remark, that the results appear to be better in the Campbell Hospital than in the European Presidency General Hospital in Calcutta (a statement which requires confirming, as we seem to remember being told by one of the officers working in the Presidency General Hospital at about the time Dr. d'Herelle was in Calcutta that they had treated successfully 33 consecutive cases of cholera); their contention that no immunity is produced in cholera and that therefore vaccination is probably useless; and the contempt with which they appear to treat the suggestion that climate can play any part in determining cholera endemicity and epidemicity, all seem to suggest that they have approached the subject with a somewhat prejudiced mind.

Their recommendations for prophylactic measures naturally consist in treating wells

and water supplies with bacteriophage; they can be summarized in their own words as follows:—

"The number of villages in which we have been able to apply the method of collective prophylaxis by bacteriophage is certainly not large enough for any definite conclusions regarding its absolute efficacy to be drawn; nevertheless it appears that these experiments tend to demonstrate it.

This method can only be applied in villages where cases of cholera occur because the bacteriophage disappears rapidly when there are no vibrios present at the expense of which it can reproduce. The method would, however, be applicable to threatened villages before cases actually occur but it would be necessary to distribute cultures of non-agglutinable vibrios isolated from carriers at the same time as cultures of bacteriophages so as to allow the bacteriophages to multiply in the intestine of the inhabitants. Such a practice would be without danger and the proof is that in all the villages when an epidemic has ceased, as well as in villages which have remained free from the disease, non-agglutinable vibrios as well as bacteriophages are found in the wells. It could not, therefore, be dangerous to reproduce experimentally conditions which occur naturally in populations which are free from the disease or which have become resistant.

In a town with a pipe water supply where an epidemic breaks out cultures would naturally be poured into the reservoirs to ensure the dissemination of the bacteriophage."

The memoir is an important one and should be read carefully by both bacteriologists and sanitarians in India. They will all, we feel sure, find some of the arguments convincing, the remainder stimulating. The study of the bacteriophage is in its infancy, and theory regarding it occupies a very important place. In support of each theory the writers give one, at least, and often many, examples, but this does not convince the scientist. The fact that in ten fatal cases of cholera ultra-pure, that is bacteriophage-free, cultures of vibrio were obtained means nothing to him; what he wants to know is out of 100 fatal cases of cholera from how many would an ultra-pure culture of vibrios be obtained. The impression that one gets is that there are no exceptions and that everything works exactly to plan. The experienced research worker knows that in actual practice this never occurs, and so after reading this memoir he is rather liable to feel that his intelligence has been insulted. In its exposition of the theory of the bacteriophage the memoir is rather more of a "primer" as we have already said, than a treatise, but after all that is probably what the authors meant it to be.

SPECIAL ARTICLES.

GYNÆCOLOGY AND TROPICAL DISEASES IN SHAKESPEARE.*

By V. B. GREEN-ARMYTAGE, M.D., F.R.C.P. (Lond.),

LIEUTENANT-COLONEL, I.M.S.,

Professor of Midwifery and Gynæcology, Calcutta Medical College, and Surgeon to the Eden Hospital for Women, Calcutta.

TWO YEARS ago I had the honour of speaking to this Society of the medical lore found in the Bible. To-night I am hoping to interest you in some aspects of medicine portrayed by Shakespeare.

I expect that most of you are aware that books have been written suggesting that the Bard of Avon was lawyer, soldier, courtier, gardener or astronomer, and yet, such was his genius, that I hope almost to persuade you that he was a doctor.

In the thirty-six plays mention is found of practically all the diseases and drugs known in this time, and in *Troilus and Cressida*, V. i., you will find a long list of such ills as the flesh was then heir to. But quite apart from such record, it is astounding to discover the wonderful knowledge of physiology, pathology, and psychology to which the plays bear witness. Let us acclaim him in his own words "How noble in reason, how infinite in faculty, in apprehension how like a god."

William Shakespeare was born on 23rd April, 1564, and died on the anniversary of his birth in 1618, that is twelve years before Harvey published to the world his momentous discovery of the circulation of the blood. But it should be remembered that for thirty years the poet was mixing constantly with the keenest brains of the realm, both in and out of London on his theatrical tours, and that that was the glorious Elizabethan age when merchant venturers, fired by the voyage of Hakluyt and "the new map with the augmentation of the Indies" (*Twelfth Night*) were seeking trade facilities with the distant West and East.

Surely then it needs but little imagination to picture the returning wanderers in the convivial company of Shakespeare and his player friends at the Mermaid, exchanging their tales of courts, courtesans and countries.

Those were the days of the Renaissance of Medicine as of Art, when such famous men as Fallopius, Vesalius, Fabricius, Columbus and Montanus had begun scientific dissection of the cadaver, and it is by no means improbable that Shakespeare heard of these men, or saw engravings of their discoveries in some London printing house with which he was in close touch throughout his life. Nor, in assessing his knowledge of medicine, must it be forgotten that his eldest daughter Susannah married Dr. John Hall in 1607, and that therefore some of his wealth of clinical observation may be attributed to this close association with one of the profession, although the greater number of his plays were written before that date.

In the thirty-six plays, seven regular physicians are mentioned but, be it noted, no surgeon, except it be that Dick Surgeon in *Twelfth Night*, who was so intoxicated that he could not attend his duties. You will remember the lines

"Didst see Dick Surgeon, sot?"

"Oh, he's drunk Sir Toby, an hour ago, his eyes, were set at eight in the morning. He's a rogue."

At that time, besides physicians licensed to practise by the College of Physicians or Company of Barber Surgeons, there were a host of quacks, both male and female, allowed by Act of Parliament in 1543 the liberty to practise, "if they had knowledge and experience of the nature of roots, herbs and waters, and of the operation of the same." As instances of these, you will remember Dr. Pinch in *The Comedy of Errors*, Friar Laurence in *Romeo and Juliet*, the female water

caster in *Twelfth Night*, Helena in *All's Well that Ends Well*. It is possible that Shakespeare also put Dr. Caius in *The Merry Wives of Windsor* in this category, for when the learned doctor boasts of his surgical skill and threatens to remove the testicles of Sir Hugh Evans for interfering with his love affairs, he is dubbed "belly stale," "a Castalian King Urinal" and "Monsieur Mockwater," though I must say I have a liking for that one small meed of praise he earns from the innkeeper.

"Shall I lose my doctor? No, he gives me the potions and the motions."

Early Marriage.

Before speaking of tropical medicine, it will perhaps be convenient to illustrate the poet's knowledge of gynæcology.

In Elizabethan times, as in India to-day, early marriage was the rule rather than the exception, but it is obvious that the dangers thereof were recognised, for in *Romeo and Juliet*, I. iii., speaking of Juliet, Capulet says to Paris:—

"My child is yet a stranger in the world,

She hath not seen the change of fourteen years,

Let two more summers wither in their pride,

Ere we may think her ripe to be a bride."

To which Paris replies:—

"Younger than she are happy mothers made" and Capulet retorts

"And too soon marred are those so early made."

And in the next scene Lady Capulet says to Juliet:—

"We'll think of marriage now,

Younger than you are made already mothers,

By my count, I was your mother much upon these years,

That you are now a maid."

Quickening.

There are two references to this, one in *Love's Labour Lost*, V. ii.:—

"Faith, unless you play the honest Trojan, the poor wench is cast away, she's quick, the child brags in her belly already, she's yours."

And the other in *A Comedy of Errors*, I. i.:—

".....till my factor's death, Drew from me the kindly embracements of my spouse

From whom my absence was not six months old

Before herself, almost fainting under the pleasing

Punishment that women bear, became a joyful

Mother of two goodly sons,

And which was strange, the one so like the other

As could not be distinguished but by name."

Obviously a case of uniovular twins.

Longings of Pregnancy.

The only mention of this condition that I can find is rather a quaint one in II. i.:—*Measure for Measure*,

"Sir, she came in great with child, and longing, save your honour's reverence, for stewed prunes. Sir, we had but two in the house, in a fruit dish, a dish of some three pence, your honours have seen such dishes, they are not China dishes, but very good dishes."

These lines would appear to indicate that regular traffic with the East was quite usual in 1608 when this play was written.

Parity of Ages in Husband and Wife.

In 1582 Shakespeare married Anne Hathaway who was eight years his senior. The marriage, judging by the bard's absences and his will, cannot be considered a happy one: you will remember that all he left her was his second best bed.

I think he nicely points the physiological moral of their disparity in ages in those lines in *Twelfth Night*, II. iv., which were written in 1600:—

"Too old by heaven. Let still the woman take

An elder than herself, so wears she to him,

So sways she level in her husband's heart,

For boy, however we do praise ourselves,

Our fancies are more giddy and infirm

Than woman's are."

* A paper read before the Medical Section of the Asiatic Society of Bengal on 20th January, 1930.

Death of the Fetus.

Or its macerated retention *in utero*—probably due to syphilis—is put forward by *Henry VIII.* II. iv., as an excuse for his divorce from Katherine of Aragon:—

"Who hath commanded Nature that my lady's womb,

If it conceived a male child by me, should
Do no more offices of life to it than
The grave does not to the dead; for her male issue
Ere died ere they were made, or shortly after
This world had aired them."

And in *Henry VI.* Part 3, IV. iv., Queen Elizabeth bemoans the disastrous effect of acute emotion upon the child within her, in the lines:—

"Fair hope must hinder Life's decay,
And I the rather wean me from despair
For love of Edward's offering in my womb,
This is it that makes me bridle passion,
And bear with mildness my misfortune's cross,
Lest with my sighs or tears I blast or drown
King Edward's fruit, true heir to England's crown."

Of course I need not remind you that the idea of the infant being born as the poet says:—

"Full of unpleasing blots and sightless stains,
Lame, foolish, crooked, swart, prodigious,
Patched with foul moles and eye offending marks—
as a result of pre-natal influence still holds to-day though we are unaware of any scientific explanation

Premature Birth.

That premature birth may occur from the rolling of a ship, will be of interest to many mothers proceeding home from India, for it is described in *Pericles*, III. i.:

".....Lucina, O
Divinest patroness and midwife gentle,
To those that cry by night, deliver thy deity
Aboard our dancing boat, make swift the pangs
Of my queen's travails."

And in *A Winter's Tale*, II. ii., fear and grief at being cast into prison causes Queen Hermione to have a precipitate and premature labour:—

"How fares our gracious lady?"
"As well as one so great and so forlorn
May hold together, on her frights and grief,
Which never tender lady hath borne greater,
She is something before her time delivered"

Toxæmia of Pregnancy.

Although the line I am going to quote was not written with reference to conception, it so beautifully gilds the picture of a woman pregnant, with anxiety and sickness, that I feel compelled to make use of it, for who in India has not seen the sallow icteric face of the unwilling mother. The line is from *Troilus and Cressida*, I. iii.:—

"What grief hath set the jaundice on your cheeks"

Labour.

The references to difficult labour are interesting to us for as I pointed out in my former address, there are very few instances in the Bible of dystocia, and but of two deaths following confinement, the one from exhaustion and the other probably from inversion of the uterus or post-partum hæmorrhage. But as I then remarked, this absence of any record of difficult labour is what one would expect of primitive people living active, healthy, nomadic lives. Conditions were probably much the same in country districts and among the well-to-do of Merrie England, so perhaps we should not expect sweet Master Shakespeare to mention difficult labour. If death in child-bed were common, it is hardly likely, considering the enormous wealth of medical lore he gives us, that he would have omitted to make use of the fact in one or other of the plays.

On the other hand, this is perhaps surprising when we remember that rickets, one of the commonest causes of dystocia, existed in the crowded areas of the larger towns in the poet's time, for within 60 years of his death, the first authenticated description of rickets, *alias* the "English disease" was written by Dr. Glisson.

In *Henry VIII.* V. i., the agony of Anne Boleyn at the birth of the future Queen Elizabeth of England is described:—

".....the Queen's in labour,
They say in great extremity, and feared
She'll with the labour end."

And in contrast it is rather amusing in the last lines of the same scene to observe the disgust of His Majesty when he was told by the garrulous old lady that he had a daughter:

"As like you as a cherry is to cherry."

It is of interest to note that in *Henry VI.* Part 3, V. vi., the birth of Gloucester is described as ill-omened and difficult in the lines:—

"Thy mother felt more than a mother's pain,
And yet brought forth less than a mother's hope,
To wit, an indigested and unformed lump."

And later in the same scene we are told in his own words that he was a footling presentation and born with teeth:—

"For I have often heard my mother say
I came into the world with my legs forward,
The midwife wondered, and the women cried
'O Jesus bless us he is born with teeth,'
And so I was. Which plainly signified
That I should snarl and bite and play the dog."

Again, it would appear from *Richard III.* IV. iv., that not only does the poet describe the birth of Gloucester as difficult, but it looks as if it was a case of oligoamion and that this was the cause of the deformities, for we read in *Henry VI.* Part 3, III. ii., the words:—

"She did corrupt frail nature with some bribe,
To shrink mine arm up like a wither'd shrub,
To make an envious mountain on my back
Where sits deformity to mock my body,
To shape my legs of an unequal size,
To disproportion in every part."

Moreover it would seem that it was recognised that the fetus could be deformed or strangled by morbid conditions *in utero*, for we have the lines in *Richard III.* IV. iv.:—

"Oh, that she might have intercepted thee
By strangling thee in her accursed womb."

Which would suggest strangulation by the umbilical cord.

Cæsarean Section.

There seems little doubt that this operation was well known and talked about in the days of Shakespeare, for not only are there two actual references in the plays, but an expression is used metaphorically in *King John*, V. iii., which would indicate that his audience was well acquainted with the operation. The lines are:—

"You bloody Neros, ripping up the womb
Of your dear mother England, blush for shame."

And although Shakespeare may have had "little Latin and less Greek," it is quite probable that he had heard of those lines in *Ovid* (*Metam. Lib.* 2. l. 630):—

*Nature flammis uteroque parentis,
Eripuit geminique tulit Chironis in antrum.*

Which indicate that Aesculapius was cut from his mother's womb. Perhaps you will let me remind you of the story, that Coronis, the mother of the unborn Aesculapius by Apollo, was killed by Artemis for unfaithfulness. Her body was about to be burnt on the pyre, when Apollo snatched the boy from his mother's womb (and the flames) and carried him to the cave of the wise Centaur Chiron, who instructed him in the cure of all diseases, and so he became the great god of medicine to the Greeks.

The operation is of great antiquity, and I think it is to the credit of the Church of Rome that it popularised and countenanced it in mediæval days, doubtless in the teeth of violent hostility. Mr. Herbert Spencer tells us that we owe the title "Cæsarean Section" to a Jesuit priest Theophile Raynaud, who published a

memoir in 1637 entitled *De ortu infantium contra naturam per sectionem Cæsaream tractatio*. Anyhow it can safely be assumed that the popular idea which labels Julius Cæsar as the first living result of the operation is erroneous, for historically we know his mother lived long after his birth, and had rumour or tradition of such an operation surrounded him, surely Plutarch would have mentioned it and Shakespeare touched upon it in his play. As a matter of interest, it is possible that the word Cæsarean is a play upon the Latin verb *cædo*.

Mr. Herbert Spencer tells us that the first authentic record of Cæsarean section, with the recovery of mother and child, is by Bauhinus. The operation was performed by a sow gelder, Jacob Nufer of Siegershausen, who, after thirteen midwives and several lithotomists had failed to deliver or relieve his wife, decided to operate with a razor *non secus quam porco*. The child lived to the age of 77, the mother recovered and later was delivered of twins, and four other children were born naturally after them. So you see, even in those days "once a Cæsarean, did not mean always a Cæsarean."

The question now arises, whether in his plays Shakespeare refers to the classical operation, or to post-mortem Cæsarean section for you remember that in *Macbeth*, V. vii., the Thane of Glamis boasts:—

"I bear a charmed life, which must not yield
To one of woman born."

To which Macduff replies:—

"Despair thy charm,
And let the angel whom thou still hast served
Tell thee, Macduff was from his mother's womb
Untimely ripp'd."

To my mind, the interpretation of these lines is that the mother of Macduff perished prematurely or in labour, and, in obedience to the edicts of Holy Mother Church, the baby was cut from her womb.

Again, in *Cymbeline*, V. iv., we have the lines:—

"Lucina lent me not her aid,
But took me in her throes,
That from me was Posthumus ripp'd
Came crying 'mongst his foes,
A thing of pity."

This, together with the lines in I. i.:—

".....for which their father
Then old and fond of issue, took such sorrow
That he quit being, and his gentle lady
Big of this gentleman, our theme, deceased
As he was born. The king he takes the babe
To his protection, calls him Posthumus Leonatus."

Would seem to leave no shadow of doubt that the poet infers post-mortem Cæsarean section, from the play upon the name Posthumus, and the word ripp'd, cf. *cripuit* in the lines of *Ovid*.

The First Cry of the Infant.

I feel that many a mother in the anxious moments immediately following child birth, when the baby's life is in doubt, will appreciate the lines in *King Lear*, IV. vi.:—

"Thou know'st the first time we smell the air
We wawl and cry,
When we are born we cry that we are come
To this great stage of fools."

Lactation.

It is interesting to read that Juliet was not weaned until she was three years old. The poet states that the nurse had to put wormwood on her nipples in order to wean the child:—

"When it did taste the wormwood on the nipple
Of my dug, and felt it bitter, pretty fool,
To see it tetchy and fall out with the dug."

Despite the prolonged lactation, Juliet does not appear to have been very rickety, for in the same scene we read:—

"For then she could stand alone, nay be the rood
She could have run and waddled all about."

Sterility.

In mediæval times there existed, as there does in India to-day, a belief in the efficacy of charms and erotic flagellation for the cure of this condition. In *Julius Cæsar*, I. ii., Shakespeare makes use of Plutarch's description of the feast Lupercalia, in order to remedy Calphurnia's sterility. Let me quote you the passage from Plutarch:—

"In those days many young noblemen and magistrates ran up and down the city with their upper garments off, striking all they met with thongs of hide by way of sport, and many women, even of the highest rank, placed themselves in the way and held out their hands to the lash, as boys in school do to the master, out of the belief that it procures an easy labour for those who are with child, and makes those conceive who are barren."

I'm sure you will like that reference to the boy and his schoolmaster written in A.D. 100, and will wish that there were more of this nowadays in our schools.

The lines of Shakespeare are:—

"Forget not in your speed Antonius
To touch Calphurnia, for our elders say
The barren, touched in this body chase
Shake off their sterile curse."

Aphrodisiacs.

Throughout the ages much trust has been placed in the doubtful efficacy of such substances. For instance, in *The Merry Wives of Windsor*, V. v., we have the invocation of Falstaff:—

"Let the sky rain potatoes, let it thunder to the tune of Green Sleeves, hail kissing comfits, snow eringoes, let there come a tempest of provocation, I will shelter me here."

The potato of that time was the sweet potato, *Convolvulus battatus*, which like the eringo (sea holly) had the reputation of being able to restore decayed vigor. Of course I need not remind you that our potato of to-day is the *Solanum tuberosum*, and with tobacco, was originally brought from Virginia by Sir Walter Raleigh.

It may interest some of you to know that the tune of Green Sleeves is an old ballad entered at Stationers' Hall in 1580, the words and tune of which are still extant.

Again in *Othello*, I. i., Brabantio infers a secret knowledge of aids to concupiscence when he says:—

"Are there not charms,
By which the property of youth and maidenhood
May be abused. Have you not heard, Roderigo,
Of some such thing?"

And later he accuses Othello of influencing Desdemona:—

"Thou has practised on her with foul charms,
Abused her delicate youth with drugs, or minerals
That weaken motion."

Midwives.

References to midwives are numerous, and it is probable that Shakespeare was thinking of these women when he wrote in *Twelfth Night*, IV. iv.:—

"Carry his water to the wise women."

But it would appear that the "wise women" were like Dickens' Sarah Gamp, too prone to liquid refreshment, for in the same play II, v., Marcius says:—

"Nay, but say true, does it work upon him?"

And Sir Toby answers:—

"Like *aqua vitæ* on a midwife."

The midwife of those days apparently exhibited a trait perhaps not altogether obsolete to-day, loquacity, but alas, with us the punishment does not fit the crime. For instance, in *Titus Andronicus*, IV. ii., because she was "a long tongued babbling gossip," the midwife was murdered in order to stay the evidence of illegitimacy in her patient!

But against this, there are those lines in *Romeo and Juliet*, I. iv., referring to Queen Mab as the fairies' midwife:—

"This is the hag, when maids lie on their back
That presses them, and learns them first to bear,
Making them women of good carriage."

Medico-Legal.

Apart from the reference in *The Winter's Tale*, II. ii., where Paulina asseverates the law of all countries of all times, that a woman pregnant cannot suffer capital punishment, in the lines:—

"This child was prisoner to the womb and is
By law and process of great nature, thence
Freed and enfranchised, not a party to
The anger of the king, nor guilty of
If any be, the trespass of the queen."

There is the claim of Joan of Arc in *Henry VI*, Part I. V. v., exemption from execution, on the plea of pregnancy:—

"I am with child, ye bloody homicides
Murder not then the fruit within my womb,
Although ye hale me to a violent death."

It is only fair to Shakespeare's memory to state that eminent modern scholars doubt whether he was the author of the above episode in this play. They aver that the original manuscript was tinkered with, and its author accepted the idle rumours of her enemies against the Maid, just as we accepted the most amazing reports about the Germans in the Great War. For if you will read Andrew Lang's masterpiece *The Maid of France*, you will see that there is irrefutable evidence produced of her austere chastity throughout life, and you will recall her last piteous appeal:—

"Alas will they treat me so horribly and cruelly
and burn my body, that never was corrupted, and
consume it to ashes this day."

Although not strictly relevant to gynaecology, it is a curious fact that the poet should allude in *Cymbeline*, I. iv., to animal experimentation for the purpose of discovering the potency of drugs. Perhaps he had read, or heard of the experiments of the perfidious Caesar Borgia, for in the same play he describes the effects of chronic arsenic poisoning.

"A mortal mineral, which being took should by
the minute, feed on life, and lingering, by inches
waste you."

Of acute arsenic poisoning, he gives a vivid description in *King John*, V. vi.

There are several other references to poisonous drugs in use at that time, for instance the line in *Hamlet*, IV. vii.

"I have bought an unction of a mountebank"
would seem to indicate curare, whereas the words I

"With juice of cursed hebenon in a vial"
must mean hemlock (*Conium*) which you will remember Socrates died of. The lines in *Macbeth*, I. iii.,

"Have we eaten of the insane root
That takes the reason prisoner"
refers of course to Henbane (*Hyoscyamus*)

"which if it be eaten or dronke, it breedeth madness
or slow likeness of sleepe."

Personally, speaking of drugs, the line that I like best is that appeal of Cleopatra to Charmian

"Give me to drink mandragora,
That I might sleep out this great gap of time
My Anthony is away."

Though perhaps Iago's description in *Othello*, III. iii., is almost as fine

"Not poppy nor mandragora,
Nor all the drowsy syrups of the world,
Shall ever medicine thee to that sweet sleep
Which thou ow'dst yesterday."

It may interest you to know that Mandragora or Mandrake, was the antispasmodic that Reuben gave to Leah, and which was so helpful to Rachel in *Genesis*, XXX, 14.

And Reuben went in the days of wheat harvest and found mandrakes in the field, and brought them unto his mother Leah. Then Rachel said to Leah.

"Give me I pray thee of thy son's mandrakes."
"And Jacob slept that night with Leah and she conceived." And later also "Rachel conceived."

*Diseases met with in the Tropics.**Malaria.*

In the low-lying and undrained areas of England, malaria was more or less endemic in the days of Shakespeare, consequently it is not surprising to find in his plays numerous references to this disease. The general opinion in those days—which held till the discoveries of Laveran and Ross, was that malaria arose from inhaling the miasma of sun warmed swamps, for in the *Tempest*, II. ii., Caliban says

"All the infections that the sun sucks up
From bogs, fens, flats, on Prosper fall
And make him by inchmeal a disease."

and again in *Julius Caesar*, II. i.

"Is Brutus sick, and is it physical to walk
unbrae'd, and suck up the humours
Of the dark morning."

To dare the vile contagion of the night,
And tempt the rheumy and unpurg'd air,
To add unto his sickness"

and in *King Lear*, II. iv.

"..... infect her beauty
You fen sucked fogs, drawn by the powerful sun
To fall and blast her pride."

Further, in *Timon of Athens*, IV. iii.

"O blessed breeding sun, draw from the earth
Rotten humidity, below thy sisters orb
Infect the air."

The various clinical types of fever are recognised in several places. For instance in *Henry V*, II. i., Dame Quickly speaks of Falstaff as

"So shaken of a burning quotidian, that it is most
lamentable to behold."

In *Richard II*, II. i., we read of the death of John of Gaunt

"presuming on an ague's privilege"

also in *Julius Caesar*, I. ii., we have reference to the rigor, pallor, and wasting after malaria in the lines

"When the fit was on him I did mark
How he did shake, his coward lips
Did from their colour fly,
And that same eye did lose his lustre, I did

hear him groan
And that tongue of his, alas it cried
Give me some drink, Titinius."
also in II. ii.

"Caesar was ne'er so much your enemy
As that same ague which hath made you lean."

In *The Tempest*, III. ii., the delirium of malaria is described

"He is in his fit now, and doth not talk
after the wisest"

and in *As You Like It*, III. ii., there is that beautiful metaphor

"He seemed to have the quotidian of love upon
him, he that is so love shak'd."

It is interesting to note that in *Troilus and Cressida*, III. iii., Shakespeare recognised that an attack of ague might be precipitated by exposure to the sun—insolation—for we have the lines

"And danger, like an ague subtly taints
Even then when we sit idly in the sun."

Plague.

There are innumerable allusions to the plague, for it must be remembered that in the poet's day the City of London was rarely free from this disease. In the various references to the pestilence, it is difficult at times to know whether the poet inferred bubonic plague or typhus, for both diseases were equally common and may frustrate diagnosis even to-day. For instance, in *Coriolanus*, IV. i.

"Now the red pestilence strike all trades in
Rome, their occupations perish."

and in *The Tempest*, I. ii.

"The red plague rid you for learning me
your language"

and in *Troilus and Cressida*, II. i.

"A red murrain on thy jades tricks"

and in iii.

"He is so plaguey proud, that the death tokens cry 'No recovery.'" Whatever the actual disease, it is obvious that it was then recognised as being very infectious, for in *Twelfth Night*, I. iv., we read

"Even so quickly may one catch the plague" and in *Richard II*, I. iii.

"Suppose devouring pestilence hangs in our air, And thou art flying to a fresher clime."

In this connection it is of great interest that Shakespeare should refer to two methods of treatment which were as common then as they are in the East to-day, for in *Coriolanus*, III. i., we read of segregation in the case of infectious diseases

"Pursue him to his house lest his infection, being of catching nature, spread further." whereas in *Romeo and Juliet*, V. ii., infected individuals are forcibly interned in their own house

"..... the searchers of the town Suspecting that we both were in a house Where the infectious pestilence did reign, Sealed up the doors and would not let us forth."

Finally, while speaking of quarantine, perhaps you will allow me to quote Shakespeare's dear thought of England and his appreciation of our island home being segregated from the external world, in those lines from *Richard II*, II. i.

"This fortress built by nature for herself, Against infection and the hand of war."

Dysentery.

There are but few allusions to this malady, which considering the many scenes of camps and battle, is perhaps remarkable, but there is the following line in *Titus Andronicus*, III. i.

"My bowels cannot hide her woes, But like a drunkard must I vomit them" and in *Troilus and Cressida*, II. ii.

"No lady of more softer bowels, more spongy to suck in the sense of fear."

I have often wondered why some modern pill vendor, or patient with chronic constipation has not adopted Hamlet's words

"For this relief, much thanks."

Anæmia.

We have noted the pallor which the poet associated with malaria, but it is obvious that he had observed chlorosis, or secondary anæmia of women, as a thing quite apart from the same condition in men, for in *Twelfth Night*, II. iv., we have those beautiful lines

"..... she never told her love But let concealment like a worm i' the bud Feed on her damask cheek, she pined in thought And, with a green and yellow melancholy, She sat like patience on a monument Smiling at grief"

and in *Romeo and Juliet*, IV. i., the still more beautiful lines

"The roses in thy lips and cheeks Shall turn to paly ashes."

Whereas in *Henry IV*, Part 2, IV. iii., Falstaff refers to male green sickness in words which are, I think, of particular interest to us in Bengal.

"For thin drink doth so overcool their blood, and making many fish meals they fall into a kind of male green sickness, and then when they marry they get wenches. They are generally fools and cowards, which some of us should be, but for inflammation."

And in *Anthony and Cleopatra*, III. ii., we read

"And Lepidus is troubled with the green sickness."

Consumption.

First we have those lovely lines in *A Winter's Tale*, IV. iii., which are so peculiarly applicable to the zenana world of India

"..... pale primroses That die unmarried, ere they can behold Bright Phoebus in his strength, a malady Most incident to maids."

and then, in *Troilus and Cressida*, V. iii., the wasting of consumption, as possibly complicating syphilis or malaria is described

"A whoreson ptisick, a whoreson rascally ptisick so troubles me, and I have such an rheum in mine eyes and ache in mine bones, that unless a man were cursed, I cannot tell what to think on it"

again, in *A Lover's Complaint* we find a reference which may be construed to mean the fetid breath of the consumptive.

"Oh, that sad breath his spongy lungs bestowed."

Hydrophobia.

It is obvious that this was well known to follow the bite of a rabid dog, for in *The Comedy of Errors*, V. i., we have the lines

"The venom clamours of a jealous woman, Poison more deadly than a mad dog's tooth."

Pyorrhœa.

I expect most of you are aware that the modern tooth brush came into fashion about 1700. Prior to this little care was taken of the teeth except perhaps the occasional use of the stick customary in India to-day. It is however probable that caries was rare in those days because of breast feeding, a full vitaminic diet and the scant use of knife and fork, but there can be little doubt that pyorrhœa did exist, for we have the lines in *Coriolanus*, II. iii.,

"Bid them wash their faces and keep their teeth clean,"

and in *Julius Cæsar*, I. ii., Casca says

"The rabblement uttered such a deal of stinking breath."

Moreover you will remember in *The Merry Wives of Windsor*, Falstaff speaks of "kissing comfits," which refers to a custom of taking perfumed cachous to sweeten the breath, a habit referred to in *Romeo and Juliet*, I. iv.

"Because their breaths with sweetmeats tainted are."

In the epilogue to *As You Like It*, it would appear that halotitis was unpleasantly common in Elizabethan days, for Rosalind says,

"If I were a woman, I would kiss as many of you as had breaths that I desired not."

Finally we have those caustic lines in the 130th Sonnet which Mr. G. B. Shaw observes is such anathema to women,

"And in some perfumes is there more delight Than the breath that from my mistress reeks."

Syphilis.

There are so many references to this malady under various titles such as "the French disease," the "rotten disease of the South," "the Neapolitan disease" that I need not detail them, except perhaps in the interests of syphilographers to say that the most arresting are to be found in *Hamlet*, V. i., *Measure for Measure*, I. ii., *Henry V*, II. ii., and *Timon of Athens*, IV. iii.

Incontinence of Urine.

You are all aware that this is a condition often seen in children and prostatic old men, but perhaps not many of you know that Shakespeare mentions the fact—which is corroborated by Ben Jonson in his play *Everyman in His Humour*, and is vouched for by the Hon. Robert Boyle,—that it is proverbial that the music of the bagpipes has the power to produce enuresis. Here are the lines in *The Merchant of Venice*, IV. i.

"Some men there are that love not a gaping pig, Some that are mad if they behold a cat, And others, when the bagpipes sing i' the nose Cannot contain their urine."

Ben Jonson's lines are

"What ails thy brother? Cannot he hold his water at the reading of a ballad?"

"Oh no, a rhyme to him is worse than cheese or a bagpipe."

Gaitre.

Shakespeare, living in Stratford, must have seen many cases of Derbyshire neck which was doubtless as common then as it is in the Darjeeling hill tracts to-day. Therefore I am sure these lines in *The Tempest*, III. iii., will appeal to you

"Who would believe that those were mountaineers.
Dewlapp'd like bulls, whose throats had hanging
At them wallets of flesh."

Pruritus.

It is obvious that scabies was known and its cause understood, for in *Romeo and Juliet*, I. iv., we have the reference

"Not half so big as a round little worm,
Prick'd from the lazy finger of a maid"
and again in *The Tempest*, II. ii.

"Yet a tailor might scratch her where'er she
did itch"
and in *Coriolanus*, I. i., Marcius says

"What's the matter, you licentious rogues, that
rubbing the poor itch of your opinion, make
yourselves scabs."

Diagnosis by the Appearance of the Urine

This is probably one of the very oldest methods of diagnosis, and as you are aware it still exists in the East amongst Ayurvedies and the followers of the Baghat. In Shakespeare's time this custom was called "water casting," and there are many references to it throughout the plays. Perhaps the best known occurs in *The Two Gentlemen of Verona*, II. i.

"These follies shine through you like water in a
urinal, that not an eye that sees you but is a physician
to comment on your malady."

Diet.

I feel sure that my Hindu and vegetarian friends will feel complimented by the lines in *Twelfth Night*, I. iii.

"I am a great eater of beef, and I believe
that does harm to my wit"
to which Sir Toby feelingly replies

"No question about it"
but they should mark well the words of Longaville in *Love's Labour Lost*, I. i.

"Fat paunches have lean pates, and dainty bits
Make rich the ribs, but bankrupt quite the wits"

On the other hand, in *Julius Caesar*, I. ii., the folly of asceticism is described as follows,

"Let me have men about me that are fat,
Sleek headed men and such as sleep o' nights.
Yon Cassius has a lean and hungry look,
Such men are dangerous."

In *The Comedy of Errors*, V. i., there is good advice for doctors and students, who as you know, due to hurried and irregular meals, are prone to suffer from indigestion and duodenal ulcer, for it is written

"Unquiet meals may give you indigestion."
and in *Macbeth*, III. iv.

"Let good digestion wait on appetite, and
health on both."

For those who are romanticists I like the words of Speed in *The Two Gentlemen of Verona*, II. i.

"Though the chameleon love, can feed on air I am
one that am nourished by my victuals, and would
fain have meat."

To show you in India, Shakespeare's appreciation of the importance of a clean milk supply, surely there is nothing to equal Launeclot's remark in III. i., of the same play,

"She can milk, look you, a sweet virtue in a
maid with clean hands."

Speaking of public health, it is of more than ordinary interest to find that even so long ago as the days of Shakespeare, flies were looked upon as carriers, for in *Romeo and Juliet*, III. iii., we have those beautiful lines

"..... more courtship lives
In carrion flies than Romeo, they may seize
On the white wonder of dear Juliet's hand
And steal immortal blessing from her lips.
Flies may do this, when I from this must fly."

Alcohol.

Merrie England in the days of Shakespeare was well noted for its beer drinking propensities, vide *Othello*, II. iii., but it is doubtful whether the mead and hop grown beer did much harm. The poet-actor-manager lived in convivial times, therefore it is a pleasure to read in *Henry VIII*, I. iv.

"Good company, good wine, good welcome,
Can make good people"

but I think our Scotch and American friends respectively will appreciate the lines in *Othello*, II. iii.

"Come lieutenant, I have a stoup of wine."

"Not to-night good Iago, I have a very poor and unhappy brain for drinking. I could well wish courtesy would invent some other form of entertainment"

but I doubt if even a Scotsman would accept the advice of Falstaff in *Henry IV*, Part 2. IV. iii.

"If I had a thousand sons the first human principle I would teach them, would be to forswear a thin potation and addict themselves to sack."

Mental Disorders.

Nothing illustrates the genius of William Shakespeare as well as his reading of the mind with the causation and development of mental diseases. To those who are particularly interested I may refer them to the book of Dr. John Bucknill published in 1867 on *The Mad Folk of Shakespeare*. For our purpose it will be sufficient to remind you that "Othello" and Julius Caesar suffered from epilepsy, which in the latter play Brutus calls "the falling sickness."

In *King Lear*, II. iv., we have the curious reference to *hysterica passio*, and in *Troilus and Cressida*, II. iii.

Ulysses describes the symptoms of Achilles in words which seems to indicate his disease as incipient general paralysis of the insane.

The tragedies of Macbeth and Hamlet portray a knowledge of psychological medicine without parallel in literature, and those of you who have had occasion to be called to such a case, will appreciate the words of the canny Scotch doctor in *Macbeth*, III. i.

"This disease is beyond my practice, I think but
dare not speak, more needs she the divine than the
physician."

as he discreetly tries to pass her on to the confessional. Moreover, I like to think that that same canny doctor perhaps originated the Rule of the Commissioners of Lunacy that we should record a patient's own words as evidence of mental instability, for you will remember he says

"I will set down what comes from her to satisfy
my remembrance the more strongly."

There seems little doubt that Shakespeare foreshadows the principles of modern psycho-analysis in those famous lines

"Canst thou not minister to a mind diseased,
Pluck from the memory a rooted sorrow,
Raze out the written troubles of the brain
And, with some sweet oblivious antidote
Cleanse the clogg'd bosom of that perilous stuff
Which weighs upon the heart"

and I feel that the authorities of all mental hospitals will rejoice that the proper treatment of mental diseases can be credited to his genius, for in *Much Ado About Nothing*, V. i., we read

"Fetter strong madness in a silken thread,
Charm ache with air, and agony with words."

There are many other references to melancholia and mania in the plays, for instance in the *Comedy of Errors*, and *King Lear*, but it is worthy of note that the poet urges the physician to be sanguine even in the

most anxious moments, for in *Love's Labour Lost*, V. ii., we read

"Your task shall be with all the fierce
endeavour of your wit,
To enforce the pain'd impotent to smile"

for "The miserable have no other medicine,
But only hope."

Finally, there are those wise lines in *King Henry IV*, Part 2, III. i., which to my mind are so apposite to the state of politics in England and India to-day:

"Thou you perceive the body of our kingdom
How foul it is, what rank diseases grow
And with what danger near the heart of it"

to which Warwick answers

"It is but as a body yet distempered,
Which to his former strength may be restored
By good advice and little medicine."

If one reads Shakespeare earnestly one realises how prophetic he is and how nearly he touches existence and customs to-day. For instance, I think he must have foreseen the modern jazz band for, although he frequently speaks of music as a remedy, he is equally emphatic that as a soothing agent it may have an opposite effect. In *Richard II*, V. v., he writes

"This music mads me; let it sound no more;
For, though it have help madmen to their wits,
In me, it seems, it will make wise men mad."

Again, he foresees modern late hours and overeating and describes an excellent remedy. Here are the lines in *Henry IV*, Part 2, IV. i.

".....We are all diseased
And, with our surfeiting, and wanton hours,
Have brought ourselves into a burning fever,
And we must bleed for it!"

Again, perhaps we owe the modern waistless line of women to Shakespeare, for we read the words of Queen Elizabeth in *Richard III*

".....Ahl cut my lace asunder,
That my pent heart may have some scope to beat."

However, it is nice to read in *The Comedy of Errors* that Dr. Pinch had a good bedside manner. The line reads

"Give me your hand and let me feel your pulse."

And the description of a lady's voice

"Her voice was ever soft,
Gentle and low, an excellent thing in woman."

Although the poet seems to appreciate the effect of the recent festive season in the line

"For my voice I have lost with hollaing and
singing of anthems"

it is obvious that Shakespeare was well aware of the benefits of fresh air, for we read such lines as

"The most wholesome physic of thy health
giving air."

"The air is quick and it pierces and sharpens
the stomach."

"There's fresher air my lord in the next chamber,
Lead in your ladies."

Finally, let us not forget those words

"Our remedies oft in ourselves do lie,
Which we ascribe to Heaven."

The poet's estimation of a patient's gratitude is as true to-day as three hundred years ago.

"Blow, blow thou winter wind,
Thou art not so unkind
As man's ingratitude."

But, remember he does not overestimate the help of medicine, for we read

".....I consider
By medicine life may be prolong'd, yet death
Will seize the doctor too."

Prognosis.

It is said of Sir William Osler that he never saw a patient, however desperately ill, without leaving behind him an atmosphere of hope. The same idea is to be found in *Anthony and Cleopatra*, II. v.

"Though it be honest, it is never good
To bring bad news"

for we read in *Henry IV*, Part 2, I. i.

"He that but fears the thing he would not know,
Hath by instinct, knowledge from others eyes
That what he feared, is chanced."

It is worthy of note that the poet well understood the importance of the previous history of adjudging disease, for in *Henry IV*, Part 2, III. i., we read

"There is a history in all men's lives
Figuring the nature of the times deceased,
The which observed, a man may prophesy
With a near aim, of the main chance of things
As not yet come to life."

Gentlemen, the time allotted me is coming to an end, and you remember what Lord Say remarked in *Henry VI*

"Long sittings to determine poor men's causes,
Hath made me full of sickness and diseases."

Nevertheless, I trust you will not think of me as

"A fellow of infinite jest and most excellent fancy"

who "waxes desperate with imagination,"
but rather believe that

"My endeavour has been

To frame your mind to mirth and merriment,
Which bars a thousand harms, and lengthens life"

and so

"Give me commendation for my free
entertainment."

I know I have but touched upon the fringe of this great subject and my thesis is but a thing of "shreds and patches," but if I have awakened fresh interest in the world's greatest poetic genius, I shall consider myself sufficiently rewarded.

THE VALUE OF MEDICAL SOCIETIES.*

By C. A. GILL, D.P.H.,

LIEUTENANT-COLONEL, I.M.S.,

Director of Public Health, Punjab.

LADIES AND GENTLEMEN,

It is my first and pleasing duty to offer you my cordial thanks for the honour you have done me by electing me to be your president during the ensuing year. It is an honour which I deeply appreciate, but when I accepted it I was not aware that the duties of the office embraced the delivery of a presidential address, but the Council has recently decided to add this new feature to the agenda of our annual meetings. I must therefore bow to its decision—and at the same time crave your indulgence whilst I endeavour to fulfil the duty imposed upon me. The subject upon which I propose to address you is the value of medical societies. Of societies in general, whose number is legion, I do not propose to speak. All no doubt perform useful services in greater or less degree, but there are peculiar features attaching to medical societies which render them, with due regard to the limitations

*The presidential address delivered before the Punjab Branch of the British Medical Association on 9th March, 1930.

imposed by circumstances, perhaps of greater value than any other societies of a similar nature.

Perhaps the first and most important aim of a medical society is educational. Medical science, which is the lineal descendant of that daughter of Aesculapins named Panacea, is so wide a subject, the problems which it embraces are so complex, our knowledge of disease is at once so large and yet so incomplete, our means and our methods of restoring the sick are so constantly changing, that of no learned profession more than ours can it be said, with greater truth, that our education is never complete.

But Aesculapins had another daughter whose name was Hygieia and from her is derived that branch of medical science which deals with the conservation of health. A science which embraces problems both of health and disease is therefore sufficiently abstruse and extensive; but that is not all, medicine is not only a science, but an art; it is not only a science and an art, but it is also, in some measure, a craft.

To be an expert in all branches of medicine is obviously impossible and the most we can hope to do is to keep abreast of the times in our own speciality and to learn something of what is going on in other branches of medical science. We however start our professional life under a severe handicap. It is obvious that no curriculum however long and no training however perfect can turn out graduates who are fully and for all time equipped to practice their profession. By the time we leave college we have merely learnt how to learn, but it is not easy to learn and at the same time to earn a living.

The habit of systematic reading has not always been acquired, time does not often permit of observations of scientific value being made under the conditions of every-day practice, and the tendency of the young practitioner to rest satisfied with the little knowledge he has gained at college, is strong. Who has not met doctors who call to mind Shakespeare's lines regarding

"The fashion of these times

"When none will sweat but for promotion

"And having that, do choke their service up

"Even with the having."

It is here where the medical society comes in. Much can be learnt from books and journals and from the study of cases, but the medical society offers a unique opportunity to the medical man of improving his knowledge at little or no cost and with the least possible effort to himself. Those in government service can, it is true, obtain study leave once or twice in their service and some form of post-graduate study is obligatory in most branches of government service, but the private practitioner is not so fortunate. He can rarely take leave, lest his practice takes leave of him.

To all members of the medical profession, and more especially to the private medical practitioner, the medical society is therefore a boon, if not a necessity. It is not merely the knowledge acquired by attendance at clinical meetings and demonstrations—though it may be considerable—that has to be taken into account, but the fact of being an active member of a medical society tends to keep the mind of the doctor receptive and to prevent him from adopting an attitude of complacency towards his professional attainments.

It was these considerations that promoted some of us a few years ago either to form a new medical society in Lahore or to resuscitate the Punjab Branch of the British Medical Association. The latter seemed the easier course and, thanks largely to the active interest and support of the Principal and staff of the King Edward Medical College, and more especially of the devoted labours of Lieut.-Col. Harper Nelson, our indefatigable Secretary, the Punjab Branch of the British Medical Association can claim to be one of the most flourishing and most active branches of the association in existence. But, gentlemen, have we done enough? Lahore is only one city in the Punjab—and in the *mofussil* the lamp of medical science burns none too brightly. Divisions ought to be formed in other cities, more especially in Amritsar and Ludhiana where there are medical schools. We might, too, publish our

transactions, in which not only the scientific papers read at our fortnightly and other meetings might be published, but also other matters of local interest to the profession.

The functions of a medical society are however not merely educational. By the very nature of things medical men, engaged in private or consultant practice, are involved in a more or less intense struggle for existence—a circumstance which too often leads to strife and personal animosities. Sometimes the trouble is due to misunderstandings, sometimes to ignorance, sometimes to pettiness, and at others to less venial causes. But too often the result is that the unity of the profession is compromised and its interests jeopardized. In such circumstances it may well happen that a chance meeting in the neutral atmosphere of a medical society may lead to explanations and reconciliations. Here, too, an opportunity is afforded of establishing those personal relationship and friendships, which appear to be the best method of solving the communal problem, which in medicine, as in other walks of life, is a grave handicap to progress.

Another function of a medical society is to promote the honour and corporate interests of the profession, but here let me tell a story and sound a note of warning. An Englishman, a Frenchman and a German were once asked to contribute to the literature of the elephant.

The Englishman selected as his title:—

"Elephants I have shot, with an appendix on the ivory trade."

The title selected by the Frenchman was:—

"Samson, The amours of an elephant."

The German, in collaboration with 27 friends, produced 6 bulky tomes in 24 parts with the title:—

"A Handbook on Elephants in Health and Disease. Their History, Life, Death and Metaphysical Implications, with some account of the Giraffe and the Rhinoceros."

I do not know what title an Indian would have selected, but in the year of grace 1930, I apprehend it may have taken the form of:—

"The Elephant considered as a politically minded animal, with special reference to its employment in twisting the British Lion's tail."

Gentlemen, the story, like every good story, conveys a moral. The moral is that there is no place for politics in a well-conducted medical society. I do not wish to suggest that politics should be eschewed entirely, but I do hold that a medical society should not degenerate into a political arena and that its political activities should be confined to actions calculated to promote the unity, honour and interests of the profession.

This surely must be our guiding principle. It is, indeed, obvious that, in the absence of a spirit of concord and unity, it is not possible to build up a strong and independent medical profession.

Medical science recognises no boundaries, political, topographical or ethnological, and its votaries must seek knowledge from whatever quarter it may be obtained. For this reason the tendency, which has recently become prominent, to adopt an attitude of isolation must be regarded as a grave error.

Englishmen, Americans and others go to Moga to sit at the feet of Raj Bahadur Dr. Mathra Das—and Indian practitioners would surely be well advised to maintain, socially and scientifically, a close relationship with all that is progressive in the scientific world. "In essentials unity, in non-essentials, liberty—and in all things charity" is not a bad motto for a medical, and, indeed, for many other societies. It seems to me, therefore, that those who seek to divide the profession and destroy its unity are doing no good to themselves and an ill-service to their country, whilst those who are working to make the Indian medical profession strong and self-sufficient are the only true "independence-wallahs" amongst us!

Gentlemen, this address has already been sufficiently long, but before I conclude let me refer briefly to one

more respect in which medical societies, and for that matter all societies, are worthy of our active support.

The success of any society is in large measure dependent upon its office bearers and upon those who devote their time and energy, by giving lectures or demonstrations, to promoting the objects of the society.

This work—voluntary and unpaid—is often considerable, but when it is undertaken in the public interest, when private advantage is subordinated to the public good, surely then it may be said that it blesses him who gives as well as him who receives. The medical society may therefore be said to promote the spirit of social service, which in its broader aspects implies good citizenship.

To conclude, I have placed before you in barest outline the varied functions—educational, social and ethical—that medical societies subserve. I have done so not because I have anything novel or original to say, but because I feel, at this particular juncture, it may be conducive to the honour of the profession and the interest of this country to emphasize the important values for which a well-conducted medical society stands.

Medical News.

ASSOCIATION FOR THE PREVENTION OF BLINDNESS IN BENGAL.

Inaugural meeting held at Government House, Calcutta.

AN inaugural meeting for the formation of the Association for the Prevention of Blindness in Bengal was held at Government House on 26th March, 1930, at 6 p.m. under the presidency of the Hon'ble Lady Jackson. Among those present were:—

The Hon'ble Sir George Rankin.
The Hon'ble Maharajah Sir P. C. Tagore.
The Hon'ble F. A. Sachse, Esqr.
The Hon'ble Sir C. C. Ghosh.
The Hon'ble Mr. Justice D. N. Mitter.
Mrs. F. V. Rushforth.
Mrs. Cottle.
Lieut.-Col. D. P. Gail, I.M.S.
Lieut.-Col. W. L. Harrett, I.M.S.
Lieut.-Col. E. O'G. Kirwan, I.M.S.
Dr. C. A. Bentley.
Dr. H. Subrawardy.
Dr. T. Ahmed.
Dr. A. K. H. Pollock.
Dr. Kedar Nath Das.
Dr. T. N. Majumdar.
Dr. Rai Haridhore Dutt Bahadur.

The meeting opened with an address from the Hon'ble Lady Jackson in which she stated:

"Ladies and gentlemen:

This meeting has been called to inaugurate an Association for the Prevention of Blindness in Bengal.

You are all aware that the terrible calamity of blindness is very prevalent in this country, but many of you probably do not know that a large percentage of cases could have been prevented by simple treatment in the early stages, and that many others can be cured by suitable operations and other forms of treatment. The object of this Association will be to spread the knowledge that blindness is preventable and curable and it is hoped that this will be done by methods of education, by practical demonstration and eventually by means of travelling hospitals and dispensaries. Colonel Kirwan will explain to you the chief causes of blindness and will indicate the lines upon which the Association should attack the problem.

We hope to form a strong committee which will be able to carry out the objects for which we are holding this inauguration meeting to-day. I shall now call on Colonel Kirwan to read a paper on Blindness in India."

Following the address Lieutenant-Colonel E. O'G. Kirwan, I.M.S., read a paper on Blindness in India in course of which he said:

"It is not generally known to what an extent blindness prevails in India. The medical man only sees the cases who come to him for operation or treatment. He does not see the vastly greater number of people suffering from eye diseases who do not avail themselves of medical assistance, due to ignorance, apathy or poverty."

"For India the figure of totally blind persons in the census returns showed an incidence of about 1½ per thousand. The population of Bengal is 46½ millions and the incidence of total blindness is 0.7 per thousand, but the returns for the compilation and application of vital statistics are inaccurate and unreliable. It is no exaggeration to say that the true ophthalmic picture of India should be represented by figures showing 1½ millions of totally blind persons and 4½ million persons with more or less impaired eyesight. No one who has not worked in India could form any conception of the enormous amount of preventable and curable blindness which overshadowed the health, happiness and usefulness of the country." "It is little realised" continued the speaker "how many of the blind of all ages are capable of cure and to what an extent blindness is preventable. Blindness for the most part is preventable if the people are sufficiently educated to adopt simple precautions and to avail themselves of medical assistance, even when this would involve some trouble and a little expense."

"Blindness amongst Europeans in India and educated Indians is rare. The Indian peasant fails to realize the danger of eye complaints which if neglected may lead to blindness even when medical facilities are near at hand, and will often fail to avail himself of them, and when, for a complaint which he may regard as trivial, he has to travel many miles and to a distant dispensary, it is not a matter of surprise that he remains in his village and suffers the consequences of his neglect. Government hospitals and dispensaries may be well attended by patients for various complaints and may be very popular, but for eye diseases, the number who will attend constantly and regularly is very small compared with the frequency of these complaints."

The speaker went on "The Indian public prefers medical facilities brought to their very doors, and many eyes are destroyed by the travelling quack who visits the villages and persuades the trusting patients to submit to his unskilled operations. In large centres there are many excellent clinics and hospitals where skilled treatment is obtainable, but in country districts and villages skilled advice is unobtainable except by long distance journeys which the poor cannot afford, and so the quack visits the villages and finds ready victims who place their trust in him only to find that their plight has been made worse than before."

The broad lines on which a campaign for the prevention of blindness should be conducted were stated thus:

"1. Preventive work against ophthalmia neonatorum in cities in collaboration with municipal authorities and to extend the work to villages.

2. To find out the blind and to bring the benefits of modern surgery to them; in part at least this might be done by travelling ophthalmic surgeons and by financial assistance to the poorer sufferers to enable them to attend eye hospitals.

3. By establishing ophthalmic dispensaries in each district.

4. The system of health visitors who would visit and encourage the people to send the afflicted to hospitals for treatment early before their sight is lost."

Next Colonel Kirwan compared the condition of Egypt to that of India as regards blindness and its prevention and showed what good can be achieved by small beginnings.

The speaker concluded by quoting Lieut.-Col. R. E. Wright, I.M.S., of Madras, "intensive propaganda work is urgently required. Money spent in this connection would be better spent than in establishing institutions for the blind (i.e., training schools, homes, etc.), which,

although humane in intention, is beginning at the wrong end. The support of propaganda efforts has up to now been unenthusiastic."

A resolution, as follows, was then moved by the Hon'ble Maharajah Prodyot Coomarr Tagore, seconded by Mr. T. D. Edelston and was carried unanimously.

Resolution:

"That a Society be formed under the patronage of the Hon'ble Lady Jackson to be called the Association for the Prevention of Blindness in Bengal and the same to be registered under the Societies Registration Act 1860, with a Memorandum of Association and rules in accordance with the draft now submitted."

The Hon'ble Mr. F. A. Sachse proposed that the following be appointed Officers of the Committee of the Association:

President:

The Hon'ble Sir George Rankin, *Kt.*

Vice-Presidents:

Sir R. N. Mookerjee, *K.C.I.E., K.C.V.O.*

Sir Onkar Mull Jatia, *Kt.*

Members of the Committee:

Mrs. M. R. Mehta.

Mrs. M. L. Mitra.

Mrs. F. V. Rushforth.

T. D. Edelston, *Esqr.*

Dr. C. A. Bentley, *C.I.E., D.T.M. & H., D.P.H., M.B.*

Dr. H. Subhawardy, *O.B.E., M.D., F.R.C.S.I., D.P.H.*

Honorary Treasurer:

Capt. A. E. Ker, *v.c.*

Honorary Secretary:

Lieut.-Col. E. O'G. Kirwan, *F.R.C.S.I., I.M.S.*

The resolution was seconded by Dr. Kedar Nath Das and was carried unanimously.

HEALTH IN THE TROPICS.

THE RESPONSIBILITY OF EMPLOYERS.

THE Director of the London School of Hygiene and Tropical Medicine, Sir Andrew Balfour, gave a lecture and cinema demonstration at the School, on the 26th February, 1930. Brig.-Genl. Sir Samuel Wilson, the Permanent Under Secretary of State for the Colonies, was in the Chair, and there was a large attendance, fully representative of industrial organisations with interests in tropical countries. The lecture was intended as an introduction to the next course of lectures given at the School on Tropical Hygiene for men and women outside the medical profession taking up life in the tropics. This course is given in a series of eight lectures of one-and-a-half hours each between March 12th and 21st, and other courses will be given at regular intervals. Full particulars can be obtained from the Secretary of the Institution, at Keppel Street, Gower Street, W.C.1.

Sir Andrew Balfour in the course of his lecture said:—

"It is amazing the difference which good health makes to the tropical resident even if the climate be vile, the food unattractive and the conditions of life calculated to worry and annoy him.

"It is scarcely necessary to say that things have changed greatly for the better in the tropics since the mid-Victorian novelists used them as a background for their heroes, their heroines and their villains. Drinking habits have radically changed, the progress of civilization has effected a veritable revolution in many parts and, above all, research has thrown a flood of light into dark places and, together with experience, has taught us how to master and how to prevent disease.

"Just think for a moment what the last three-and-a-half decades have witnessed in the way of important and life-saving discoveries. The problem of malaria infection and transmission has been solved and this, in large measure, clears up the mystery which for so long a time shrouded the dreaded blackwater fever, for the

latter is now definitely known to be an expression of malarin—in other words it is a condition resulting from malaria infection.

"Yellow fever, that Yellow Jack which used to play havoc with the mercantile marine, sweeping away ships' crews and ruining trade, has been proved to be a mosquito-borne disease and so can, in most places, be readily controlled.

"Turning now to certain diseases which more especially attack the native, are in consequence foes to industry on the large scale and about which those who employ labour in the tropics should be fully informed, it is surely gratifying to realize that hookworm infection need no longer be the curse of the agriculturist.

"Here is a case in point, an extract from a letter sent by an employer to the Director, Medical and Health Department, Kenya Colony. It is culled from the *Kenya Medical Report* for 1928:

"I think that the following facts re my labourers (Wadigo) will interest you:

"Last year, and during the first six months of this year, the highest weeding and clearing task that I was able to get done by my labourers was 450 square yards per day, and this after infinite trouble. The task was done unwillingly and the men were sulky and appeared to me to be unfit to do a fair day's work.

"On the 13th May, 1928, as you no doubt remember, I took every man to your camp, where you gave them anti-hookworm treatment.

"At the present time these same labourers are doing a task of 1,000 square yards in heavier grass and bush and are doing it cheerfully."

"Quite apart from the advance in our knowledge of how to prevent and cure disease, physiological research has taught us a good deal about how best to live in hot climates—what type of house to build, what kind of clothes to wear, what kind of exercise to take and when and how to take it, what food and drink we should there consume for our benefit and comfort.

"These things being so it is amazing how many young men and women go out to posts in the tropics woefully ignorant of the A. B. and C. of tropical life. Too often they pay for this ignorance and, if so, they usually pay early in their careers, for experience teaches, but experience is apt to be a costly teacher. Nobody wishes to frighten the would-be tropical resident. Indeed, he can be assured that, apart from certain parasitic infections, he is unlikely to contract any of the more serious tropical diseases, for these find happy hunting grounds under conditions which the average European will not tolerate. Still some of the parasitic diseases such as malaria and dysentery are far from negligible and forewarned is forearmed. Furthermore a man can settle down much more quickly in the tropics and he is much happier and more comfortable there if he knows how to take care of himself and succeeds in avoiding infection, while, if he has to look after a labour force he will do so much more efficiently if he has some idea of how to safeguard its health and knows what are the dangers and difficulties which have to be avoided.

"It is surely essential to give the layman or laywoman destined for the torrid zone a chance to acquire that information which has been gained by careful and laborious work and which has wrought such a change in our tropical outlook. To me it seems almost criminal to withhold it, for I have seen time and again what I may call the tragedy of ignorance. I have seen a white missionary sitting in the smudge of a fire like any naked native to save himself from mosquito bites because he had not realized that in certain parts of Africa life after sunset is unendurable without a net.

"What is one to say of the tragic case of the foolish youth who finds in the company of some native woman a relief from loneliness and an outlook for his passions, and lives to regret for ever his lack of comprehension as to what this kind of cohabitation may mean both morally and physically?

"On employers there seems to me to rest a serious responsibility, while in any case a policy of neglecting to take advantage of any means whereby the health

of an employee may be conserved is beyond question shortsighted. If the first wealth be health in this part of the world, still more does health spell money in countries where the resident is in any case somewhat handicapped and where even minor maladies are put to assume dimensions to which they are strangers in more favoured climes.

"In the lectures given at this School that fact is borne in mind and the tropics are considered from several angles in an introductory address which has much to commend it. Then the student is warned how to prepare for his journey and for life in a hot country. He is advised as to outfit and various measures of prophylaxis, both before quitting England and during the voyage. Thereafter personal hygiene in the tropics is considered in all its bearings and he is given many "tips," the outcome of experience which cannot fail to be useful to him wherever he may happen to be stationed. Some of the commoner diseases of the tropics, especially those from which he may himself suffer, are then expounded and general measures of protection against tropical diseases are fully explained, including those which must be taken when camping out. A section deals with insects and other pests and the price of failure to cope with malign climatic conditions and disease is indicated in no uncertain terms. Finally, simple and explicit instructions in prevention and in first aid complete a course carefully adapted to the needs of the layman and calculated both to interest and benefit him.

THE OFFICE INTERNATIONAL D'HYGIENE PUBLIQUE.

The following is an abstract from the report by Lieut.-Col. Phipson, D.S.O., M.D., M.R.C.P., I.M.S., delegate for the Government of India, on the session of the Office International d'Hygiene Publique held at Paris, October 21st to 30th, 1929.

The first plenary session was held at the premises of the Office at 3 p.m. on Monday, 21st October. Monsieur Velghe (Belgium) in the Chair. The President opened the proceedings by referring in sympathetic terms to the loss which the Committee had sustained in the recent death of Dr. H. M. Gram, delegate for Norway, and welcomed his successor, Dr. Wehring. He also extended a welcome to Dr. Shanin Pasha, delegate for Egypt, and the newly appointed members of the Committee. The full list of delegates is appended to this report. He then reviewed the general activities of the Office since the last session, and detailed the personnel of the five Commissions dealing with Smallpox, Quarantine, Opium, the Pilgrimage and Yellow Fever. As delegate for India I continued to serve on the last four of these.

In the following account of the work of the session I do not propose to follow the discussions which took place from day to day, but to summarise the conclusions of the conference and to indicate the general trend of the discussions.

Item I.—Application of the International Convention of 1926 and questions connected with it—

A. (i) *Report of the Egyptian Quarantine Board on the pilgrimage of 1929.*—The important report on this subject, presented by Major Gilmour, President of the Board, was considered and approved and the Committee recorded their appreciation of this valuable documentation. The Committee were further indebted to Major Gilmour for giving the delegates an opportunity of witnessing an interesting cinematographic film dealing with the work of the Quarantine Station at El Tor.

A. (ii) *The Pilgrimage.*—Major Gilmour's report and the general questions relating to the pilgrimage were examined by the Pilgrimage Commission under the Chairmanship of Sir George Buchanan. So far as could be stated from reports hitherto received, no important diseases other than smallpox and dysentery were prevalent in the Hedjaz during the period of the pilgrimage of 1929. The Commission noted the advantages in Syria, Palestine, Irak and Transjordan, as well as to the pilgrims themselves from

the Beyrout Conference and its association with the Regional Bureau, and it was suggested by the delegate for Egypt, that, in view of the happy results already achieved, it would be advantageous to consider the convocation, in the near future, of another conference of countries in the Near East, on the lines of the recent conference at Beyrout, at which it was hoped that Persia would participate, to consider the directions in which further progress might usefully be attempted, as for example the selection and regulation of pilgrim routes.

Sanitary Control at El Tor.—The Commission noted the cases of S.S. "Riad" and S.S. "Plata" referred to at page 48 of Major Gilmour's report, which afford an additional proof of the necessity for continual vigilance at El Tor and Kamaran with the object of detecting ships which fail to comply with the requirements of the International Sanitary Convention.

Measures in the Red Sea.—The communication from Dr. Atkey, delegate of the Soudan, was noted with interest. This dealt with improvements in the quarantine establishment at Suakin and in measures taken with regard to pilgrim traffic including the cessation of pilgrim transport by dhows and other sailing vessels. Dr. Lutrario, the Italian delegate, intimated that measures were being taken at Massawah to put an end to that form of transport as regards pilgrims from Erythrea.

I was able to state that as far as Aden was concerned there is no mass transport of pilgrims from Aden to Jeddah otherwise than via Kamaran, but there are no doubt means of reaching Jeddah from the Hadramout by an indirect route without calling at Aden.

Use of Kamaran Hospital accommodation for cases other than Plague or Cholera.—In reply to a question by the Delegate of the Dutch East Indies, the Commission expressed its view that it was clearly the intention of the Convention of 1926 that suspected cases of smallpox on ships should be treated on shore at the Kamaran Quarantine Hospital, but that as regards diseases other than those specified in the convention, it was a matter which concerned the captain of the ship, the hospital authorities and the pilgrim himself. Regarding the pilgrimage from India, I informed the Conference that the Haj Enquiry Committee (under the Chairmanship of the Honourable Mr. H. B. Clayton) recently appointed by the Government of India, had begun its labours. It is not clear from the terms of reference of this Committee, whether such matters as sanitary passports for pilgrims will be considered by this Committee, but it would appear appropriate that the Government of India should give this matter their attention with a view to the establishment of a system of sanitary passports similar to that in force in all important countries with Mohammedan populations. In view of the apprehension with which traffic of all kinds from India is apt to be regarded in the international atmosphere of the "Office," it seems desirable that the Government of India should go as far as they can to meet what is evidently international feeling in the matter.

The question of sanitary passports for pilgrims was studied at the last session of the Office, and was again considered at this session. The consensus of opinion was then, and is now, that although a form of sanitary passport identical for all countries concerned with pilgrim traffic may be found impracticable, it is at least very desirable that all countries should have a system of sanitary passports for pilgrims, and that these documents should resemble each other as nearly as the particular requirements of each country will permit.

A. (iii) *Application of Article 28 of the International Convention of 1926.*—This subject assumed considerable importance owing to the divergence of practice in the interpretation of the article. The matter was discussed by the Quarantine Commission under the Chairmanship of Dr. Jitta (Holland) and the text of its report should be read in this connection.

A. (iv) *Use of Wireless Telegraphy in Quarantine Operations.*—On this subject the Quarantine Commission had before them a communication from the

Spanish delegate, and a comprehensive note by Dr. Philip Stock (Delegate for South Africa) including a draft Code of brief and practical questions, the answers to which are intended to be sent by wireless from ships not more than 12 hours or less than 4 hours before arrival in port, the message to be preceded by the code word "Moden" which has been provisionally allotted for this purpose by the International Code of Signals Committee. The note also included a copy of the Quarantine portion of the Draft Medical Section of the International Code of Signals. Dr. Stock's draft code was accepted by the Committee who emphasised that the adoption of such a system was manifestly to the advantage of shipping and of Port authorities, and would naturally facilitate quarantine operations, and expedite the granting of pratique. They reiterated, however, their former view that it could not be considered practicable to confer on ships, on the strength of a wireless sanitary declaration, any definite rights as regards pratique on arrival in port.

A. (v) *Ship's Doctors*.—This question is at present in suspense, and further communications are awaited from delegates of the countries concerned. The Committee propose to reinforce the action already taken by the Office by calling attention to the matter when issuing the "Report to Governments."

The question is already receiving attention by the British Government particularly as regards professional instruction for ships' surgeons, in the form of an optional diploma.

A. (vi) *Bills of Health*.—There is still but little unanimity on this subject though there is an evident tendency towards reduction of cost, and towards the suppression of consular visas.

A. (vii) *Sanitary Control of Aerial Navigation*.—On this important subject the Committee had the advantage of hearing an interesting statement made at the invitation of the Office by Monsieur Roper, Secretary-General of the International Committee of Aerial Navigation. He outlined the present position of aerial navigation and its future development, new and projected air-routes and air-ports, the development or direct wireless communication between aerodromes, and the working of the International Committee. Communications from the Japanese delegate, the delegate of the Belgian Congo and an important note by the Director of the Office were read and discussed at length. The possibility of the spread of cholera by the air-route from Karachi to Egypt and other countries was the basis of much discussion and, as delegate for India, I should have liked to be in a position to reassure the delegates more effectively than was possible with the information at my disposal, that the risk of spread of cholera was in reality very remote. Such material points as (1) the sanitary condition of the Karachi air-port and its situation with respect to the infected part of the city; (2) the category of passengers who use the air-route; (3) the absence of any dangerous communication between pilots and passengers arriving at Karachi preparatory to departure by air and the infected part of the city; (4) the water supply of the air-port and of Karachi hotels, and the nature of water supplied to aeroplanes before leaving such points presented on the basis of known rather than assumed fact would have gone far to reinforce the tendency of the majority of the delegates to regard the restrictive measures adopted against Karachi in Egypt and elsewhere, as hardly justified by the circumstances.

The Commission, however, considered that the subject was of such great importance that it was incumbent on the Office to study the matter in all its bearings by means of a special Commission of Aerial Navigation, which would meet before the beginning of the next Session and present its report at the meeting of the Office in May 1930. The Commission were further of opinion that no attempt should be made, in devising a sanitary code for aerial navigation, to assimilate it to the maritime code.

A. (viii) *Rat-guards*.—At the last session of the Office Dr. Park (Delegate for Australia) was invited

to prepare a report on this subject, and his report was considered, together with the communications from India by Dr. Chitre and Major Taylor and one from Dr. Rupert Blue, regarding a type of rat-guard in use in the Philippines by the Quarantine Commission which formulated certain conclusions, which were later adopted by the full Conference.

These were briefly as follows:—

(a) Rat-guards are only of use if suitably constructed and if the greatest care is used in applying them;

(b) The Commission does not recommend any standard pattern: Port authorities may employ either the cone or disc provided it is constructed in accordance with the principles laid down in the report of Dr. Park;

(c) The Commission hopes that the electric rat-guard devised by Major Taylor and Dr. Chitre, will be put to practical test under working conditions;

(d) The Commission has learnt with interest of the suggestion of Dr. Boye that strongly illuminated hemispherical guards might be effective, having regard to the well-known effect of glare and dazzle on the lower animals, and hopes that experiments may be instituted on these lines.

Item II.—Opium Commission.—The Opium Commission under the Presidency of Dr. Carriere reviewed the list of new products resulting from the combination of morphine with organic acids, and recommended that all preparations of this type should be examined with a view to their ultimate control.

Item III.—Yellow Fever.—On this subject there were several important papers for discussion; these included General Boye's paper dealing with yellow fever in French West Africa, Sir George Buchanan's dealing with British West Africa submitted on behalf of the Colonial Office, Dr. Van Campenhout's on prophylaxis, and on the 1928 outbreak at Matadi, and Dr. Barrand's paper dealing with the Yellow Fever problem as affecting India. Dr. Van Campenhout's views on Yellow Fever prophylaxis led to considerable discussion, particularly as regards transmission by aircraft. The Commission under the presidency of Colonel S. P. James after a full discussion, decided to summarise the present position as regards transmission of yellow fever in the form of seven provisional conclusions, which are of such importance that I translate them *in extenso*.

(1) The specific germ of yellow fever is still unknown.

(2) The disease spreads from man to man by the intermediary of *Stegomyia (Aedes) aegypti vel argenteus*. So far, the disease has never been known to develop outside regions where this species of mosquito is found.

(3) It is believed that in those countries in which yellow fever exists, the disease is maintained in an endemic form by abortive or mild cases, particularly among children and the indigenous population. These cases often pass unobserved. In the laboratory it has been demonstrated that certain species of monkeys are susceptible of being infected with the yellow fever virus, either by direct inoculation, or by the bite of an infected *Stegomyia*.

(4) In those countries in which yellow fever does not exist, the disease can only develop if it is imported:—

(a) By persons suffering from yellow fever. It is recognised that such persons cannot infect mosquitoes after the 3rd day of the illness.

(b) By infected mosquitoes. These mosquitoes only become infective between the 8th and 12th day following the ingestion of infected blood, but a mosquito once rendered infective, remains so for the rest of its life.

(5) Ordinarily, the incubation period of yellow fever is 3 or 4 days; it never exceeds 6 days.

(6) In devising measures to avoid the risk of transport of yellow fever, it is necessary to take into consideration the habits of the mosquitoes which transmit the virus. The breeding places of this mosquito are always found in the immediate neighbourhood

of houses and the adult mosquitoes very rarely quit the local area where they hatched out.

(7) The Committee draws attention to the fact that, in view of the accidents which have occurred in the course of laboratory researches on yellow fever, these researches, if carried out in countries which are free from yellow fever, but in which *Stegomyia* are present involve a real danger of the spread of the disease.

I would draw special attention to the last conclusion of the Committee, which is particularly applicable to India. The fact that the virus can be maintained in an active condition for several months and can be transported from place to place, coupled with the occurrence of unrecognised but presumably infective cases of yellow fever in laboratory workers suggests that if research on yellow fever is contemplated in Indian Laboratories, the most rigid precautions would appear to be necessary. It may be noted that the Dutch Government has already prohibited research on yellow fever in its territories except in certain laboratories in Holland.

It appears to me probable that the importation of yellow fever virus into India for research purposes is at present the only likely mode of introduction of yellow fever into India. There are at present no direct aerial lines of communication between the West African endemic areas and India and India is hardly threatened unless the East African seaboard is infected. Moreover, up to the present it is not known whether an infected *Stegomyia* can be transported long distances by aeroplane, or on board ships. The risk of introduction by human cases, owing to the limited period of infectivity in the human subject, may be negligible but the risk of introduction by infected mosquitoes, although remote, still remains a possibility, particularly in the event of the development of African transcontinental air-routes, owing to the persistence of infectivity in the infected mosquito. Research on the habits of *Stegomyia* in India and elsewhere in relation to aerodromes and aircraft, might throw light on this aspect of the matter.

Item IV.—Cholera and Plague.—Cholera.—The only communication of importance on the subject of cholera was the French translation of the work of d'Herelle, Malone and Lahiri in India which was well received. Dr. Shahn Pasha (Egypt) recalled the possibility of cholera from eating infected oysters.

Plague.—Communications were received from General Boye on the relation between pneumonic plague and temperature in Madagascar; from Dr. Tsurumi on the outbreak of Plague in Mongolia in 1928 an epidemic of septicemic plague without pneumonic manifestations or buboes, and from Dr. Columbani (Morocco) on the ambiguous results of anti-plague inoculation in an outbreak of plague in Morocco in April-June, 1929. The question of the efficacy or otherwise of anti-plague inoculation was the subject of general discussion, and I was able to record the experiences on this point in Aden in more detail and with more accuracy than was possible at the previous session, and the marked effect of inoculation on the incidence of the disease. The possibility of diffusion of plague by means of the human flea was discussed by Dr. Columbani (Morocco) and I brought to the notice of the Committee certain facts, tending to establish this mode of diffusion, which emerged from the Aden epidemic of 1928. Dr. Ricardo Jorge (Portugal) stated his conviction that certain limited epidemics of plague were undoubtedly due to transmission by the human flea.

Item V.—Smallpox.—There were several important communications on this head. Reports invited at the last session on the administrative aspect of smallpox were received from the delegates of Great Britain, Germany, Norway and Spain. I presented Colonel Graham's report on the smallpox epidemic in Aden in 1929, and Dr. Jitta (Holland) read a preliminary communication on the quite recent epidemic of smallpox

(alastrim) in Holland. The last paper lead to an interesting discussion.

The epidemic began by the importation of a mild case of doubtful nature, in the person of a sailor arriving in Rotterdam from the Dutch East Indies. This case led to an outbreak which after much discussion was first diagnosed as "alastrim" and all the official measures applicable to smallpox were not taken although vaccination was pressed from the beginning. Later on the advice of a commission it was decided that it should be termed "variola minor." Vaccinations to the number of 1,800,000 were carried out, and there were 95 cases of post-vaccinal encephalitis.

It is recognised that the question of post-vaccinal encephalitis is still acute and it is proposed to collect and correlate information received from all sources on this important matter. The delegates of Great Britain, Holland and Germany are invited to institute histological researches to determine whether the lesions of experimental vaccinal encephalitis in the rabbit are identical with the lesions of post-vaccinal encephalitis in the human subject. The Commission will study the effects of vaccination modified by (a) vaccination carried out with minimum damage to the tissues; (b) smaller doses of vaccine; (c) dilution of lymph, and (d) use of sterile or killed lymph.

Item VI.—Tuberculosis.—Communications were submitted by the delegates of Norway and Great Britain on tuberculosis from the industrial standpoint, and the administrative measures taken to combat it.

Item VII.—Undulant Fever.—The chief communication was Dr. Dalrymple-Champney's report, published by the British Ministry of Health establishing that only 14 cases of undulant fever originating in England have been reported, that on the other hand, contagious abortion in cattle is widespread and that examination of a group of nearly 500 unpasteurised milk-samples indicated that about 5 per cent. of the cows were excreting *B. abortus* in their milk. The report emphasises the importance of pasteurisation of milk, though this does not of course eliminate the risk from direct contact. In contrast to the comparative rarity of undulant fever in Great Britain is the position in Denmark, where Dr. Madsen states that 500 cases occur annually, with a mortality of 2-3 per cent. The prevalence, so far as it is not due to direct animal-infection, as in butchers, he attributes to the distaste of Danish people for boiled or pasteurised milk, though he was careful to emphasise that all milk and butter for export is pasteurised. The incidence in Switzerland, Sweden, America and Germany were discussed by the respective delegates. Investigations are proceeding in all these countries. There is a tendency to regard *Brucella melitensis*, *Brucella abortus* and the bacillus of Bang as variants of the same organism but the circumstances in which *B. abortus* infection in animals can cause undulant fever in the human subject remain obscure. All delegates were agreed on the extreme importance of pasteurisation of milk supplies as a prophylactic measure.

Item VIII.—Acute Anterior Poliomyelitis.—One report on this subject was presented by the French Ministry of Hygiene. Sir George Buchanan commented on the peculiar distribution of the disease in sparsely populated rural districts and pointed out that in the neighbourhood of each notified case a number of mild cases could usually be found, so mild as to be scarcely recognisable. Epidemics were due to the existence of large numbers of healthy carriers.

Item XVI.—Miscellaneous.—Under this head Dr. Ricardo Jorge made an interesting statement on an apparently new disease known as "exanthematic fever," which might be confused with typhus fever. This fever has been reported from Lisbon, Algerian ports, Marseilles, Tunis (fièvre boutonnaire) and Madrid (fièvre exanthématique de la Méditerranée). The disease is characterised by a papulo-vesicular rash which leads to scabbing, no stupor or other mental symptoms, and a negligible mortality. The disease does not seem to be identifiable with the

so-called new disease of Bombay (of which I gave a brief account), but has many points in common with the Tsugamshi disease of Japan (Japanese river fever).

APPENDIX.

LIST OF DOCUMENTS ANNEXED TO THE REPORT.

1. Official list of Delegates.
2. Financial Report of the Director of the Office.
3. Draft Report to Participating Governments.
4. Agenda of the Conference.
5. Report of the Egyptian Quarantine Board on the Pilgrimage for the year 1929.
6. Report by Dr. Atkey on the Quarantine Station at Snakim.
7. Report of the Pilgrimage Commission.
- 7a. Report of the Pilgrimage Commission (English text).
8. Report by Dr. Stock on the use of Wireless Messages for Quarantine operations.
9. Report by the delegate for Spain on the use of Wireless Messages for Quarantine operations.
10. Note on the Quarantine Rules for Aerial Navigation in Japan.
- 10a. Note on the Quarantine Rules for Aerial Navigation in Spain.
11. Note by Dr. Van Campenhout on measures to be taken to prevent the spread of Yellow Fever by Aircraft.
12. Statement of Egyptian restrictions against arrivals from Karachi by air.
13. Office Note on Sanitary Regulations for Aerial Navigation.
14. Note by Dr. Park on Rat-guards (French text).
15. Note by Dr. Park on Rat-guards (English text).
16. Note by Dr. Rupert Blue on the Type of Rat-guard used in the Philippines.
17. Report by Dr. Chitre on observations on Rat-guards in Bombay.
18. Report by Major Taylor and Dr. Chitre on Electric Rat-guards.
19. Report of the Quarantine Commission I.
20. Report of the Quarantine Commission I (Continued).
- 20a. Report of the Quarantine Commission I (English text).
21. Note by the Spanish delegate on the application of the Opium Convention.
22. Note by Professor Lenz, on "Acedione," a new Codeine derivative.
- 22a. Report of the Opium Commission.
23. Copy of British Statutory Rules on Deratisation (No. 832 of 1929).
24. Report by Dr. Boye on Yellow Fever in French West Africa.
25. Report by Dr. de Vogel on accidental infections with Yellow Fever.
26. Report by Dr. Van Campenhout on the outbreak of Yellow Fever at Matadi, 1928.
27. Note by Dr. Van Campenhout on the prophylaxis of Yellow Fever in Africa.
28. Note by Sir George Buchanan on Yellow Fever in British West Africa.
29. Report of the Yellow Fever Commission.
- 29a. Report of the Yellow Fever Commission (English text).
30. Note by Dr. Boye on the Relation between Pneumonic Plague and Temperature.
31. Report by Dr. Tsurumi on Plague in Mongolia in 1928.
32. Note by Dr. Columbani on Anti-plague inoculation in Morocco, 1929.
33. Note by Dr. Syssine on Plague in Eastern Russia.
34. Note on Administrative measures taken against Smallpox in England and Wales.
35. Note on Administrative measures taken against Smallpox in Germany.
36. Note on Administrative measures taken against Smallpox in Norway.
37. Note on Administrative measures taken against Smallpox in Spain.
38. Note on Administrative measures taken against Smallpox in Sweden.
39. Note by Dr. Tsurumi, on the Initial Rash of Smallpox.
40. Note by Dr. Hamel on Post-Vaccinal Encephalitis in Germany.
41. Note by Dr. Kling on Post-Vaccinal Encephalitis in Sweden.
42. Report by Colonel Graham on the Epidemic of Smallpox in Aden, 1929.
43. Note by Dr. Jitta, on the outbreak of Smallpox (Alastrim) in Holland, 1929.
44. Report of the Smallpox Commission.
45. Note by Dr. Macnalty on Industry and Tuberculosis in England and Wales.
46. Note by Dr. Macnalty on Industry and Tuberculosis in England and Wales (English text).
47. Note by the late Dr. Gram on Industry and Tuberculosis in Norway.
48. Note by Dr. Hamel on Industry and Tuberculosis in Germany.
49. Note by Dr. de la Torre on Industry and Tuberculosis in Mexico.
50. Note by Dr. Syssine on the preparation of Jennerian Vaccine in Soviet Russia.
51. Note by Dr. Tsurumi on Tuberculosis Statistics in Japan.
52. Note by Dr. Boye on Tuberculosis and Vaccination with B. C. G. in West Africa.
53. Note by Dr. N. of B. C. G.
54. Note by the French Ministry of Hygiene on Acute Poliomyelitis.
55. Note by Dr. Syssine on the distribution of Hospitals in Soviet Russia.
56. Note by the delegate for Spain on the Spanish rules concerning the use of Antiseptics and colouring matters in food.
57. Note by Colonel Harrison on the Frequency of Syphilis in Great Britain.
58. Note by Dr. Hamel on the Frequency of Syphilis in Germany.
59. Note by Dr. Hamel on Tabes and General Paralysis in Germany.
60. Note by Dr. Hamel on Anti-venereal measures in Germany.
61. Note by the Office on Anti-venereal measures in France.
62. Note by Sir George Buchanan on Rural and Urban Mortality in Great Britain.
63. Office note on District Nurses in France.
64. Office note on the protection of Maternity in France.
65. Note by Dr. Raynaud on a new method of employing "Chloropierine."
66. Note by Dr. Boye on Antirabic measures in the French Colonies.
67. Note by Dr. Tsurumi on Scarlet Fever.
68. Note by Dr. Boye on Sleeping sickness in French West Africa.
69. Note by Dr. Hamel on the protection of Maternity in Germany.
70. Note by Dr. H. S. Cumming, on Sanitary Organisation in certain South American Ports.
- 71-75. Miscellaneous documents relating to the application of the International Sanitary Convention of 1926.
76. Note by Dr. Doorenbos on the rôle of Bacteriophage in Plague.
77. Health Organisation in Australian Ports. (Australian Ministry of Health.)
78. Report by Dr. Dalrymple-Champneys on Undulant Fever.

THE ROSS INSTITUTE INDUSTRIAL ANTI-MALARIAL ADVISORY COMMITTEE.

The second quarterly meeting of this committee was held on 14th October, 1929, and the third meeting on 13th January, 1930.

At the second meeting Sir Malcolm Watson dealt with conditions at Korusput. Here both malaria and blackwater fever are very prevalent. A certain amount of open drainage had been carried out by Government, but the speaker had recommended sub-soil drainage as being both cheaper and more efficient. Kuala Langat, F. M. S., a district which had at one time been freed from malaria, had now again become malarious; the attention of the F. M. S. Government had been drawn to the matter. Twelve planters from Bengal, Assam, and South India had attended the first short course of instruction; the course lasted a week, and included field demonstrations, lantern lectures, and cinema films. An increasing number of medical men were availing themselves of the facilities for the study of malariology at the Ross Institute. In Assam the malaria problem generally is a very serious one, and something in the way of a large and permanent organisation to combat malaria in that province is required; the difficulty is to get men who are capable and qualified for the work; no smaller scheme will be effective, and the whole problem merits consideration. An expedition with Sir William Simpson at its head had been sent out to examine the malaria position in an area of some 2,000 square miles on the borders of the Congo, belonging to the Roan Antelope Copper Mines and the Rhodesian Selection Trust. In Ceylon the Malaria Control Scheme was progressing favourably and extending its activities. The chairman, Mr. A. W. Still stated that the facilities at the Ross Institute were being brought to the notice of managers of rubber plantations who were on leave in the United Kingdom.

At the third meeting, the position in Assam was further considered. Reports from many gardens indicated that considerable progress was being made in controlling malaria, and Dr. G. C. Ramsay's work in Cachar was specially mentioned. With regard to Rhodesia, Sir Malcolm Watson expected to go out there in March, and to review the position. A tribute was paid to the work of the Bengal Anti-Malaria Co-operative Societies and of Rai Dr. G. C. Chatterjee Bahadur, who had been made an honorary life fellow of the Ross Institute. The malaria control at the Tata Iron and Steel Co.'s mines in Bihar under Mr. Senior-White had achieved very good results. The last short course for planters had been attended by planters from South India, Ceylon, Malaya and by doctors proceeding to Borneo. Experiments were being carried out with several different types of oils as larvicides in both India and Malaya. In Ceylon a river had been oiled for 22 miles, a special lorry with sprayer being used as an experimental measure. In Assam recent reports stated that the death rate among coolies on the tea gardens was 3 per cent. below the average for the general population on account of the better health conditions on the gardens.

THE ASSAM BRANCH OF THE ALL-INDIA MEDICAL LICENTIATES' ASSOCIATION.

We have only recently received a copy of the Proceedings of the Second Session of this Association, held at Dibrugarh on 26th and 27th May, 1929, but a short abstract of these Proceedings may be of interest to many of our readers. The meeting was held at the Berry White Medical School, under the presidency of Mr. E. S. Roffey, Secretary of the Assam Branch, India Tea Association.

In addressing the president, Dr. B. C. Dass dwelt upon the hardships of life of sub-assistant surgeons and licentiates. "Whenever there is an epidemic of cholera, smallpox, or influenza, a licentiate is the only friend, philosopher, and guide to the people in the infected villages. Cut off from all communications, deprived of the amenities of home life, he has to run from house to house, from village to village, sometimes without food or drink, risking his own life, attending to the victims of infectious diseases day and night, and submitting full reports thereof to the authorities." He also mentioned that many such licentiates had contracted fatal illness when employed on such duties.

Yet recognition of their services was but tardy. The police may be the backbone of the country, yet the medical subordinate is even more essential. A sub-assistant surgeon's pay is from Rs. 75 p.m., to Rs. 175 p.m. after 20 years' service, with a selection grade of 12 per cent. who may rise to Rs. 200 p.m., whereas sub-deputy collectors and P. W. D. overseers get from Rs. 150 to Rs. 400 p.m. Yet prices of foodstuffs and clothing are higher in Assam than in other parts of India, and educational facilities for children are few. The ten years' bond was irksome, whilst conditions of the licentiates employed on tea gardens included no security of tenure, or assured prospects with regard to promotion. The practice of appointing unqualified men to medical posts in the tea gardens is especially deplorable, as it limits employment for the qualified and opens up channels for abuses. The present type of sub-assistant surgeon's quarters is unsuitable and needs to be altered. The speaker emphasised the necessity for extending the medical course for licentiates from four years to five. Finally, the speaker emphasised the loyalty of the class of medical men for whom he spoke to Government.

The annual report for 1928 was next read. This showed that a new branch had been opened in Silchar, and 130 new members had been enrolled during the year as compared with 35 in 1927.

In his presidential address, Mr. Stuart Roffey mentioned that he had lived in the Assam Valley for more than 26 years. He pointed out that H. E. the Governor had drawn special attention in an official report to the valuable services rendered by subordinate medical officers in the anti kala-azar campaign in Assam, and dwelt on the supreme value of their work on the tea gardens. He also quoted the recorded opinions of tea garden medical officers as to the great value of the work done by licentiates. With regard to pay and prospects, it was a question of economic demand and supply. The question of excluding unregistered medical practitioners was under consideration. Taking the budget provision of the province for 1927-28 the percentage of expenditure on different heads was for medical relief 4.3, for police 9.9, for communications 11.9, for education 10.6, and for public health 1.5. These were relative proportions which required re-adjustment. It was "up to" local boards to remedy the state of affairs in the areas which they controlled.

THE FACULTY OF TROPICAL MEDICINE, BENGAL.

The following students are declared to have passed the D. T. M. Examination, Session 1930.—

Passed.

(Arranged in alphabetical order.)

1. Dr. Tara Prasanna Bhattacharjee, M.B. (Cal.), Private Practitioner.
2. Dr. Jogesh Chandra Chakravarty, II, L.M.F. (Bengal), Sub-assistant Surgeon, Govt. of Bengal.
3. Dr. Anil Krishna Choudhury, M.B. (Cal.), Private Practitioner.
4. Dr. Nirmal Chandra Choudhury, M.B. (Cal.), Medical Officer, Kelvin Jute Mills, Titagarh, 24-Parganas.
5. Dr. Nirmal Chandra Das Gupta, L.M.F. (Bengal), Sub-assistant Surgeon, Govt. of Bengal.
6. Dr. Chittaranjan Dutta, M.B. (Cal.), Assistant Surgeon, Govt. of B. & O.
7. Dr. Narayan Das Dutta, M.B. (Cal.), Assistant Surgeon, Govt. of Bengal.
8. Dr. Harold Aloysius Henry D'Silva, M.B.C.S. (Eng.), L.R.C.P. (Lond.), I.M.D., Assistant Surgeon, Govt. of India, employed under I. R. F. A.
9. Dr. Thomas Joseph D'Silva, L.C.P.S. (Bom.), I.M.D., Assistant Surgeon, Govt. of India.
10. Dr. Krishna Kishore Dutta, M.B. (Cal.), Private Practitioner.
11. Dr. Cyrill Aloysius Fegredo, L.M.F. (Bengal), Military Assistant Surgeon, I.M.D.

12. Dr. Prakas Chandra Ghosh, M.A. (Cal.), Private Practitioner.
13. Dr. Profulla Ranjan Gupta, M.A. (Cal.), Assistant Surgeon, Govt. of Assam.
14. Dr. Harbhagwan, L.S.M.F. (Punjab), I.M.D., working in the Malaria Survey of India, Central Research Institute, Kasauli.
15. Dr. Hartwant Singh, L.S.M.F. (Punjab), I.M.D., Govt. of India.
16. Dr. Bhupesh Chandra Lahiri, M.A. (Cal.), Private Practitioner.
17. Dr. Yeruva Surya Narayana Rao, M.A., B.S. (Madras), Assistant Surgeon, Govt. of Madras.
18. Dr. Rengaswami Varadaraja Narasimhulu Nayudu, L.M.P. (Madras), Medical Officer, Dhanushkodi.
19. Dr. Mattakat Govinda Pillai, M.A.S.S., Health Officer, Govt. of Madras.
20. Dr. Gunendra Nath Sen, M.B. (Cal.), Private Practitioner.
21. Dr. Neelakanta Seshadrinathan, L.M.S. (Madras), M.B.B.S. (Madras), Assistant Surgeon, Govt. of Madras.
22. Dr. Mualidhar Nanhuram Sandel, M.B.B.S. (Bom.), Assistant Surgeon, Govt. of Central Provinces.
23. Dr. Annada Prasad Sinha, M.B. (Cal.), Assistant Surgeon, Govt. of Behar & Orissa.
24. Dr. Charles George Joseph Speechly, L.M.F. (Bengal), Military Assistant Surgeon, I.M.D.
25. Dr. Eardley David Stephens, Diploma of Medical College, Madras, I.M.D., Assistant Surgeon, Govt. of India.
26. Dr. Bhupendra Nath Sur, M.B. (Cal.), Private Practitioner.
27. Dr. Kurisuveetil Paly Thomas, L.M.S. (Madras), Municipal Health Officer, Govt. of Madras.
28. Dr. U. Tin, L.M.F. (Burma), Sub-Assistant Surgeon, Govt. of Burma.
29. Dr. George Domingo Veliath, M.B.B.S., Govt. of Madras.
30. Dr. Arthur Greville Young, L.R.C.P., L.R.C.S. (Edin.), L.R.F.P.S. (Glas.), Medical Officer in charge, Kalua Mission Hospital.

Current Topics.

The Status of the Therapeutics of Irradiated Ergosterol.

By A. F. HESS, M.D., J. M. LEWIS, M.D.,
and
H. RIVKIN, B.A.

(Abstracted from *The Journ. Amer. Med. Assoc.*,
Vol. 93, No. 9, 31st August, 1929, p. 661.)

SOMEWHAT more than three years has passed since Windaus and Hess, as well as Rosentheim and Webster, reported the remarkable antirachitic activity of irradiated ergosterol.

All are agreed that irradiated ergosterol is an agent of exceptional potency and reliability in the prevention or the cure of rickets. The time is past for a discussion of this point. There are, however, several questions which demand consideration at the present time. One that has been raised repeatedly concerns the safety of this new therapeutic agent, more particularly whether there is any danger of its doing harm. A corollary of this question, and one which has been the subject of quite as much discussion, is that of the proper dosage of irradiated ergosterol. In an earlier paper we concluded that "as yet we have not sufficient clinical experience to define its proper dosage. Furthermore, the various preparations cannot be evaluated, as they have not yet been assayed on the basis of the number of 'curative units (rat)' which they contain." It was added that "the amounts now

recommended and employed are unnecessarily high," and that the time was not ripe to distribute this drug to the medical profession.

Results of Experiments with Various Preparations of Ergosterol.

During the past year we have been engaged with a further study of irradiated ergosterol, in the laboratory and the clinic. In the main, two preparations have been studied; an American product and a German product. It should be added that the manufacturers of the German preparation have realized that it was unnecessarily potent and have recently reduced its strength to about one-tenth the original. Although irradiated ergosterol has not been marketed in the United States, owing to uncertainties in regard to its dosage, it has been widely used in Germany, France and England, both in hospitals and in private practice. In this country its use has been restricted to investigative studies in numerous clinics throughout the country.

Beginning in October, a large group of infants was given either the American or the German preparation of irradiated ergosterol in various amounts, ranging from minimal doses to what might be considered generous amounts. The age of the infants ranged from about 3 to 9 months, and the medication was continued in many instances uninterruptedly from autumn until summer; in some it was begun during the course of the winter. However, in general, the duration of observation was long and embraced a period of several months.
